Despite a very low incidence, anaphylaxis (anaphylactic shock) is the most serious and life-threatening adverse effect of antibiotics. β -lactam antibiotics, in particular members of the penicillin group, primarily cause this reaction. The clinical signs include diffuse urticaria, stridor, and angioedema. Rapid pulse rate, reduced blood pressure, weakness, heart arrhythmias, mental confusion, and various abdominal symptoms (nausea, vomiting, diarrhea, and abdominal pain or cramping) may appear. Airway obstruction due to the glottic (laryngeal) edema and bronchospasm is an extremely important consideration due to potential fatal consequences. In the vast majority of patients, signs and symptoms appear within 60 minutes after administration. It is parenteral antibiotic administration that usually produces a rapid reaction (within 5 minutes) and therefore patients should be watched for at least 5 minutes after injection.

Anaphylaxis requires immediate professional treatment. The priority is to transfer the patient to hospital as an emergency. The patient's vital signs must be checked and emergency management started with the ABC (airway, breathing, circulation) of resuscitation. Epinephrine (1:1000, 0.5ml) should be injected intramuscularly without delay to open the airways and to raise blood pressure by constricting blood vessels until professional treatment starts. If available, corticosteroids, such as prednisone, should be given to further reduce symptoms after primary lifesaving treatment is achieved. Although it is difficult to predict the likelihood of anaphylaxis in advance, careful interview prior to use of antibiotic is important to reduce its incidence, as a history of previous anaphylaxis and poorly controlled asthma increases the risk.⁷¹ Penicillin skin testing is useful to predict the likelihood of allergic reactions to penicillin. It should be recognized that the result will not establish whether a patient will have an allergic reaction to another type of β -lactam agent.

Medical supportive care

The roles of supportive care are to improve the quality of the patient's life and to encourage resolution of the infection indirectly. These roles may include a wide range of professional and patient self-care interventions.

Inpatient management

The large majority of orofacial infections are usually managed by an outpatient practice. However, there are certain cases in which outpatient management is impracticable or unnecessarily risky. The conditions requiring hospitalisation are listed in Table 29.14.

Management of fluid balance and nutrition

Fever increases fluid loss and calorific needs. Moreover, patients may often have inadequate fluid and nutritional intake, because of poor appetite resulting from sickness and mental depression, oral dysfunction (trismus and difficulty swallowing), and pain. As a consequence, hyponutrition and dehydration may occur. It is worth highlighting that children are much more susceptible to fluid depletion as a result of dehydration and become toxic faster than adults. Patients should be encouraged to drink plenty of water and take sufficient nutrition from meals, high-calorie nutritional supplements or confectioneries. If a patient cannot take adequate fluid and nutrition, hospitalization and professional supportive care, including enteral nutrition and intravenous fluid supplementation, are required.

Pain control

A NSAID is commonly used for pain control. NSAIDs have significant toxicities and risk of side-effects. Careful prescription is required. Paracetamol has generally less toxicity, and therefore it should be administered first. Prescription of a NSAID (recommended drugs may vary between countries) should be considered for control of more severe pain. Some appropriate regimens are presented in Table 29.15. In odontogenic infections, occlusal equilibration may be

Table 29.14 Criteria for hospital admission.

Need for urgent life-saving care, high risk of fatal condition or suspected serious complication
Considerable systemic inflammatory reaction in terms of fever or malaise
Significant trismus, dysphagia or dyspnea
Severe, rapid progressive or extensively spreading infection
Need for intravenous antibiotics
Significant dehydration or malnutrition that may require professional supportive care
Suspected reduced resistance to infection
Need for surgery under general anesthesia

Table 29.15 Appropriate analgesic regimens for management of pain caused by infection.

The first choice regimen		
Paracetamol	2 tablets (500 mg per tablet)	Up to 4 times daily
For moderate pain that may not be managed with paracetamol		
Aspirin	1 tablet (300 mg per tablet)	Up to 4 times daily
Ibuprofen	1 tablet (400 mg per tablet)	Up to 3 times daily
For severe pain that requires a more potent NSAID for its management		
Diclofenac	1 tablet (50 mg per tablet)	Up to 3 times daily
For moderate to severe pain in patients in whom NSAIDs are contraindicated		
Co-codamol	1 tablet	Up to 3 times daily

Regimens are for adults.

A tablet of co-codamol contains 30 mg of codeine phosphate and 500 mg of paracetamol.

effective to reduce pain that may increase when biting or chewing.

Fever control

Mildly elevated body temperature may be of benefit to host defense mechanisms, as immune reactions may be enhanced with elevation of temperature and some pathogens with strict temperature preferences could be hindered by a small rise in temperature. Therefore if the body temperature does not exceed 38.5°C or if the patient has no complaint of fever, control of fever may be unnecessary. Paracetamol and NSAIDs are simple and effective for an unacceptable fever. Overly cold water could stimulate shivering and even increase heat production.

Patient monitoring and evaluation of response to treatment

Once treatment has started, the patient should be carefully and frequently monitored to assess the response to treatment and the occurrence of any complications, side-effects or toxic reactions to the administered medicine. This is achieved through monitoring clinical signs and symptoms (for example, changes in vital signs, extent of swelling and redness, nature of swelling and pain, body temperature, dysfunction level and the patient's subjective feelings of improvement, and blood test data). It should be noted that a patient's condition can become dramatically worse and be more serious in only a matter of hours. More careful monitoring and special attention is required in cases of severe, rapidly progressing infection and immunocompromised patients. In contrast, patients with mild

Table 29.16 Likely reasons for failure of treatment of oral and maxillofacial suppurative infection.

A substantial residual collection of pus (inadequate or insufficient surgical drainage)
Persistence of infection cause or involved foreign body
Impaired host defense mechanisms
Antibiotic factors:
No compliance of patient with prescription order/suggestion
Inadequate dose of antibiotic or insufficient level of antibiotic in infection site
Wrong bacterial diagnosis
Involvement of antibiotic-resistant microorganism

infections without any risk factors may need only self-evaluation at home and return to the clinic for review 2 or 3 days after the original therapy.

In infection without complication, provided that adequate surgical drainage has been achieved, improvement will begin by the second day of therapy. However, in the early stages of infection that appears as cellulitis, drainage of pus is usually not possible. In this case, an antibiotic may be the principle treatment, and it takes several days to determine the actual outcome of such antibiotic therapy. Therefore the treatment regimen should not be changed within short periods, unless a dramatic and rapid deterioration of the condition occurs or an indication of a side-effect or complication appears. Even though improvement may not be obtained in the first 1–2 days, the clinician should resist a temptation to change treatment regimen. Osteomyelitis, maxillary sinusitis, and actinomycosis tend to respond to treatment slower than common odontogenic infections.

If clinical improvement is not seen after an adequate period (usually 48–72 hours after start of treatment), failure of the treatment may be suspected. The most likely cause is inadequate surgical treatment (Table 29.16). Careful re-examination for any undetected abscesses is required. Extraction of the offending tooth should be reconsidered if salvage of the tooth was being attempted. Dental root fracture and fissure, and the presence of a foreign body may be a cause of delay in resolution, and therefore these should be removed.

Depression of the host defense mechanism can be a cause of treatment failure. Undiagnosed or overlooked diseases should be managed adequately. The patient's medical history should be reviewed again, and more careful and probing questioning should be undertaken. Patients are often unaware of pre-existing diabetes; if warranted, the blood sugar level should be checked. A fluid balance and the nutritional level should be reassessed because these factors may affect the outcome of treatment.

Factors associated with the antibiotic may be involved in failure of treatment. It is necessary to confirm if a patient has followed the prescription

order and whether the regimen is adequate. Another problem to consider is whether the antibiotic actually has reached the infection site. Inadequate antibiotic levels at the infection site due to an inadequate blood supply may result in treatment failure. In such instances, an increase in dosage or change in route of administration should be considered. The involvement of antibiotic-resistant bacteria may also be associated with failure. If the initial choice of antibiotic is suspected as being inadequate, the antibiotic should be changed. Alternative antibiotics should be chosen based on microbiologic examination. However, if adequate specimens are not available, a treatment that extends the antibacterial spectrum should be attempted. This could use an alternative antibiotic, a broad-spectrum antibiotic or therapy with a multi-drug combination.

Odontogenic infections

The majority of orofacial infections have an odontogenic origin. Strictly, the term odontogenic infection encompasses all forms of dental infectious diseases. However, odontogenic infections are primarily considered to be pus-producing infections associated with the teeth and the surrounding supportive structures and therefore dental caries and gingivitis do not fall into this category of diseases.

Odontogenic infections consist of three main types: (1) periapical abscesses, which involve necrosis of the dental pulp and subsequent infection of the root canal; (2) periodontal abscesses formed in association of periodontitis; and (3) pericoronitis, which is an infection of the pericoronal soft tissue overlying the crown of a tooth. The large majority of odontogenic infections are of periapical origin. Purulent infection associated with periapical origin is frequently described as a dentoalveolar abscess, although any pus-producing infections involving the teeth and surrounding supportive structures are often regarded as dentoalveolar abscesses.⁷²

A collection of pus constitutes an abscess which is a defensive reaction against the spread of infection. Cellulitis describes a condition where swelling occurs with no significant localization of pus and has a greater tendency for progressive spread. Almost all odontogenic infections show elements of both cellulitis and abscess formation. Infections commonly start as a cellulitis and tend to localize and develop into an abscess over a period of days.

In developed countries, the incidence of severe odontogenic infections has greatly decreased, primarily due to an improved quality and availability of dental care, widespread fluoridation of public water supplies, increased use of toothpastes containing fluoride, and the increased availability and use of antibiotics. However, it must be recognized that odontogenic infections may progress extensively and at an alarming speed and might cause serious and fatal complications.

Types of odontogenic infections

Endodontic diseases

The most common forms of endodontic diseases are pulpitis and periapical abscesses. Pulpitis is an inflammation localized only within the pulp of the offending tooth. In contrast, periapical abscesses are purulent lesions within the surrounding supportive structures around the root apex of teeth. Such abscesses are commonly formed through episodes of pulpitis and subsequent pulpal necrosis (Fig. 29.18).

Almost all endodontic diseases involve dental pulp. Healthy vital pulp is generally sterile and responds to various stimuli without an exaggerated response. Normal pulp responds to cold stimulation with slight pain that disappears within a few seconds. Although electric pulp testers for assessment of the status of pulp are available, the results are not highly reliable.

Whilst pulpitis is not an odontogenic infection, it can be misdiagnosed as a periapical disease; its discussion here is, therefore, warranted.

Fig. 29.18 The process from onset of dental caries to pulp necrosis. (a) Early stage of caries. (b) Advanced stage of caries, with possible reversible pulpitis. (c) Irreversible pulpitis with entry of bacteria into pulp cavity. (d) Pulp necrosis and formation of periapical abscess.

Pulpitis

Although various factors including physical, thermal, and chemical irritants are involved in pulpitis, bacterial factors, especially deep dental caries, are the most important in the etiology of pulpitis. Pulpal diseases range from reversible hyperemia to an irreversible pulpitis ending in necrosis. The clinical features of reversible pulpitis and irreversible pulpitis are summarized in Table 29.17. Reversible pulpitis generally produces no significant pain. On occasion, a mild painful response to stimulus (cold temperature) occurs, but this commonly subsides within a few seconds without additional pain or discomfort once the stimulus is removed.

Irreversible pulpitis is divided into acute and chronic forms. Acute pulpitis produces a throbbing and intensive pain. The pain involves an elevated pressure within the pulp cavity due to inflammation of the pulpal tissue. Since temperature increases pressure, an elevation in body temperature or application of a thermal stimulus (e.g. hot water) to the tooth may intensify the pain. Therefore patients often report that their pain becomes more intense when taking a bath, drinking alcohol or tea, or being in bed at night (body temperature is generally elevated in the evening and night). Although application of a cold liquid to the tooth sometimes reduces intensity of the pain, it may also provoke pain. Painful response to cold liquids usually lingers minutes even after the stimulus is removed. The pain is often difficult to control even with potent types of NSAIDs. As a troublesome feature, patients often misidentify the causative tooth, even confusing the maxillary tooth with mandibular one, but not the left and right sides of the mouth. This may lead to misdiagnosis in localizing the source of pain. Pulpal inflammation may affect the periodontal ligament, resulting in a painful response to mastication and the percussion test, although pulpitis does not always provide elevated sensitivity to the latter.

Chronic pulpitis usually does not produce a throbbing pain but does respond to cold and thermal

stimuli. Chronic pulpitis is often found in cases where the pulp has been exposed to the oral cavity. The disease process may occur for several months to several years, and also spontaneously transform into an acute infection.

Bacterial infection usually occurs in irreversible pulpitis. Viridans streptococci, lactobacilli, peptostreptococci, and anaerobic Gram-negative bacilli are often associated with these infections.^{73,74} Exposed dentinal tubules and direct pulpal exposure caused by operative procedures, trauma or deep dental caries can allow entry of bacteria into the pulp. Accessory and lateral canals can also provide direct channels for entry of bacteria. In the case of severe periodontitis, bacteria residing in the periodontal pocket may enter into the pulp through an accessory or lateral canal or the root apex. Infected regions of pulp will necrotize, and sooner or later necrosis will extend throughout the canal system. Once the whole pulpal system has necrotized, clinical symptoms of pulpitis will cease.

Diagnosis is based on medical history and physical examination of the reactions provoked with various stimuli (application of heat, cold, and percussion). Pulpitis does not provide a specific radiological change in the tooth and periodontal tissues. However, as pulpitis usually involves deep dental caries or severe periodontitis, radiographs can provide a precise localization of the source and determine whether inflammation has extended beyond the tooth apex.

The vitality of a pulp with reversible inflammation may be maintained by conventional and conservative dental treatment. In contrast, irreversible pulpitis requires endodontic therapy (pulpotomy or pulpectomy) or tooth extraction. As pulpitis does not respond to antibiotic therapy, systemic antibiotic is unnecessary.

Periapical abscess

Periapical abscesses are also described as periapical infections and periapical or apical periodontitis. Periapical abscesses commonly involve pulpal necro-

Table 29.17 Summary of the clinical features of reversible pulpitis, acute irreversible pulpitis, and acute periapical abscesses

	Reversible pulpitis	Irreversible pulpitis	Periapical abscess
Pulp vitality	Yes	Yes	No
Response to cold stimulation	Mild, disappearing within a few seconds	Often severe, lingering for minutes	No
Response to thermal stimulation	Little or no	Yes	No
Response to percussion test	Little or no	Sometimes yes	Yes
Pain at chewing	Little or no	Sometimes yes	Yes
Spontaneous pain	No	Yes	Yes
Enhanced pain intensity at night	No	Yes	No
Controllability of pain with NSAID	Not applicable	Often uncontrolled	Mostly controlled
Misidentification of the causative tooth	Usually no	Often yes	Usually no
Redness, tenderness, and swelling of the vestibule site	No	No	Yes
Response to antibiotic therapy	No	No	Yes

sis resulting from irreversible pulpitis, although failed endodontic treatment also induces the disease.

The necrotic pulp of the root canal serves as an important source of nutrition for microorganisms, and it is usually infected with a number of commensal oral microorganisms. Since the apical periodontal ligament is directly linked with the pulp system, the bacteria, bacterial products, and toxins released from the necrotic pulp may diffuse from the root canal into the periapical tissues with resultant development of a periapical inflammatory lesion. The host response to such an infection involves the building of a defensive barrier in an attempt to confine the pathogens and their toxins within the root canal system and periapical tissues. The most common sequelae of pulpitis is the formation of chronically inflamed periapical granulation tissue.³ Sometimes, the squamous epithelium of an apical granuloma proliferates, forming a cyst. An abscess may develop around the root of the tooth, either directly or after the formation of periapical granulomas and cysts. Chronic and asystematic episodes may continue whilst microbial homeostasis is maintained. However, once microbial homeostasis in the lesion is disrupted, the bacteria proliferate and invade the tissue, accompanied by acute inflamma-

tion. In acute periapical abscesses, the periodontal ligament is inflamed and the tooth often pushed slightly out of the tooth socket. Consequently, more intense pain during chewing and reaction to the percussion test with increased mobility of the tooth are evident. If any purulent exudate or pus penetrates the jawbone, infection may spread to intraoral or extraoral soft tissues. The natural history of progression and bacteriology of periapical abscesses is described later.

A periapical radiograph usually demonstrates radiolucency around the apex tip of the tooth. However, in cases with little destruction of periapical bone, significant change at the periapical region is not readily seen by radiographs.

Treatment options for an acute periapical abscess are discussed later. Once acute inflammation subsides, the disease is treated with endodontic therapy, apicectomy or extraction of the tooth.

Periodontal disease

Periodontal disease is a chronic infectious disorder that affects the soft tissue and bone supporting the teeth. This disease is initiated by a very complex microbial biofilm that develops on the tooth surface adjacent to the soft tissues of the periodontium. Periodontal disease often affects multiple teeth.

Periodontal diseases are generally divided into gingivitis and periodontitis. Gingivitis is the mildest form of periodontal disease, whilst periodontitis is the advanced form, and their clinical features are distinct (Fig. 29.19 and Table 29.18). In particular, occurrence of bone loss is the most important distinction between gingivitis and periodontitis (Fig. 29.20).

Periodontal disease is not necessarily a continuum from gingivitis. The duration of onset and the intensity of the periodontal inflammatory process vary considerably in individuals and also with tooth site

Fig. 29.19 Gingivitis is the mildest form of periodontal disease, with periodontitis being the advanced form. In contrast with gingivitis, periodontitis involves bone loss, which is the most important feature of the infection.

Table 29.18 Summary of clinical features of gingivitis and periodontitis.

	Gingivitis	Periodontitis*
Patient's age	Any age	Usually over 35
Gingival swelling	Yes (especially gingival margin and papilla)	Often yes, but sometimes slight swelling
Easy bleeding of gingiva	Yes	Often yes, but sometimes slight bleeding
Response to percussion test	No	Often yes
Bone loss	No	Yes
Nature of pocket	Gingival pocket due to gingival swelling	Periodontal pocket due to bone destruction
Halitosis	Generally no, but sometimes yes	Yes
Persistent metallic taste in the mouth	Generally no, but sometimes yes	Yes (depending on severity)
Gingival recession	No	Yes
Pulp vitality	Yes	Yes
Reversibility of tissue change	Yes	No
Possible cause of periodontal abscess	No	Yes
Possible cause of tooth loss	No	Yes

*Except mild cases.

Fig. 29.20 Periodontitis. (a) Gingival margin is swollen with erythema. (b) Radiograph demonstrates loss of alveolar bone supporting the affected teeth.

within the same patient. Although gingivitis and periodontitis may not be regarded as odontogenic infections, their description here is necessary, as an understanding of their pathogenesis and clinical features are important for the diagnosis of odontogenic infections. Necrotizing ulcerative gingivitis, an uncommon form of periodontal disease, is described in a separate section.

Gingivitis

Gingivitis is inflammation of the gingiva, and involves plaque that accumulates in the gingival margins due to inadequate oral hygiene. Gingivitis causes little pain in its early stages and may go unnoticed. The gingivae appear red rather than a healthy pink and become movable instead of being firm and tight against the teeth. Due to the accumulated plaque, the gingiva may bleed readily, especially during tooth brushing or eating. Gingival swelling results in an increased depth of the gingival sulcus (gingival pocket formation), but gingivitis does not result in bone loss or destruction of periodontal tissues. It is important to recognize that gingivitis itself is unlikely to be a cause of orofacial purulent infections. Misaligned teeth, the rough edges of fillings, and ill-fitting or unclean dentures, bridges, and crowns increase the risk of gingivitis because of increased plaque retention. Pregnancy, stage in menstrual cycle, use of birth control pills, the onset of puberty, and diabetes mellitus are all predisposing factors to this condition.⁷⁵ Some drugs such as phenytoin, ciclosporin and calcium channel blockers (antihypertension agents) can cause an overgrowth of gingival tissue, which may disturb the maintenance of good oral hygiene. In cases of leukemia, the gingiva may also become engorged with a leukemic infiltrate.

Gingivitis can be prevented through maintaining good oral hygiene by the patients themselves or by professional care. Gingivitis may be completely reversible with appropriate oral hygiene practice,

although excess gingival tissue caused by intake of certain drugs may need to be removed surgically.

Periodontitis and periodontal abscess

Periodontitis is a severe form of periodontal disease in which the inflammation of the gingiva extends to the supporting structures of the tooth. As with gingivitis, periodontitis primarily involves dental plaque and calculus, but other factors may also be associated with its etiology. Suggested risk factors include old age, compromised host defense, heredity, history of previous periodontitis, male gender, inadequate dental habits, poor oral hygiene and dental care, inadequate margins on crowns and dental restorations, presence of specific bacteria including *Aggregatibacter actinomycetemcomitans*, *Tannerella forsythensis*, and *Porphyromonas gingivalis*, race and ethnicity, stress, diabetes, specific systemic diseases, and tobacco smoking.^{76,77}

The most significant hallmarks of periodontitis are bone loss and formation of a periodontal pocket. Destruction of the periodontal tissues and alveolar bone loss are primarily a result of the excessive and continued host inflammatory response to bacterial products. The most common symptoms include bleeding and gingival tenderness, pain during chewing, malodor, and bad taste with accompanying gingival recession. As infection erodes the bone holding the teeth in place, affected teeth become loose and shift in their position, and eventually they may fall out or need to be extracted.

Periodontitis is classified into several subtypes.^{75,78} Chronic periodontitis is generally characterized by a slow progression of the disease. However, there may be bursts of destruction, and the rate of disease progression may be modified by local, systemic, and extrinsic factors. Chronic periodontitis was previously termed “chronic adult periodontitis”, since it is most prevalent in adults (≥ 35 years of age). However, it can be also seen in adolescents, and consequently

the age-dependent terminology has been removed. Bacterial species involved in chronic periodontitis include *Porphyromonas gingivalis*, *Tannerella forsythensis*, and *Aggregatibacter actinomycetemcomitans*. In addition, other types of bacteria such as *Campylobacter rectus*, *Eubacterium nodatum*, *Fusobacterium nucleatum*, *Prevotella intermedia*, *Peptostreptococcus micros*, and spirochetes can also be associated.⁷⁷

Aggressive periodontitis is distinct from chronic periodontitis. This disease is characterized by rapid attachment loss and bone destruction, and possible familial aggregation of disease. Other likely features include periodontal tissue destruction that is greater than would be expected given the level of local factors (plaque and calculus), elevated levels of *A. actinomycetemcomitans* or *P. gingivalis*, phagocyte abnormalities, and increased production of PGE₂ and IL-1b.⁷⁸ It is important to recognize that patients are often otherwise systemically healthy. Since aggressive periodontitis often occurs in people under 35 years of age, it was previously called “juvenile periodontitis”. However, this is not exclusive and may also be seen in older patients.

Periodontitis as a manifestation of systemic disease often occurs at a young age. Systemic diseases that affect the immune function, inflammatory response, and tissue organization can modify the onset and progression of all forms of periodontal disease. Such diseases include hematological disorders (acquired neutropenia, leukemias, and others) and genetic disorders (familial and cyclic neutropenia, Down’s syndrome, leukocyte adhesion deficiency syndromes, Papillon–Lefevre syndrome, Chediak–Higashi syndrome, histiocytosis syndrome, glycogen storage disease, infantile genetic agranulocytosis, Cohen syndrome, Ehlers–Danlos syndrome types IV and VIII, and hypophosphatasia). Management of periodontal disease under such circumstances should be carried out in conjunction with management of the associated systemic disease.

In recent decades, epidemiologic association between periodontitis and specific systemic conditions, including coronary heart disease, atherosclerosis, diabetes, and a higher risk of preterm low birth-weight babies, has been recognized (Fig. 29.21).^{79–81} However, the mechanisms for the various relationships remain unclear, and there are debates over actual impact of periodontal therapy on improvement of the systemic condition.

Diagnosis of periodontitis is based on the inspection of the teeth and gingiva, combined with probing of the pockets, measurement of their depth, and radiographic examination. Although mild to moderate periodontitis may be managed by the patient themselves or professional treatment, severe cases usually require extraction of the tooth.

Periodontal abscesses are associated with periodontal breakdown and localized pus in the gingival wall of the periodontal pocket. Acute abscesses are painful, edematous, red, shiny, and ovoid elevations

of the gingival margin and/or attached gingiva (Fig. 29.22). A disturbance of microbial homeostasis, destruction of the epithelial barrier or random events may result in proliferation of bacteria residing in the periodontal pocket, with the generation of a suppurative lesion. In particular, an obstruction in the drainage of the periodontal pocket by debris is the most common trigger for the onset of abscess formation. It should be noted that obstruction of drainage may involve calculus and debris that are pushed into gingival tissue during professional periodontal treatment such as scaling and root planing. Although periodontal abscesses are closely associated with periodontitis, the bacteriology is more similar to periapical abscesses than periodontitis. A well localized, small abscess can easily be managed with surgical drainage without administration of systemic antibiotics.

Pericoronitis

Since the oral hygiene around third molars tends to decline due to anatomic reasons, the gingivae surrounding the crown of the third molar often become inflamed. This condition is called *pericoronitis* (Fig. 29.23). *Pericoronitis* commonly occurs with the mandibular wisdom tooth that has not fully emerged. The flap of gingiva over the partially emerged tooth can trap fluids, food debris, and bacteria. In cases where the maxillary third molar emerges before the mandibular one, the cusp of the former can damage the flap of the latter, causing irritation. Once the drainage of exudate from the gingival pocket is blocked by impaction of foreign bodies or by trauma-induced swelling of the operculum, an acute infection may occur. The bacteriology of *pericoronitis* is similar to that of other forms of odontogenic infections.

Pericoronitis typically occurs in teenagers and young adults, presenting shortly after the third molars start erupting. It presents as an erythematous, tender, sessile swelling of gingiva and the retromolar pad. *Pericoronitis* does not often progress into the development of an abscess. Acute *pericoronitis* provides a quite intense pain that may radiate to the external neck, the throat, the ear, and the oral floor. Since the third molar is adjacent to the muscles of mastication, infection often affects the muscles, especially the medial pterygoid muscle, resulting in trismus. *Pericoronitis* of the mandibular third molar can become serious since infection may readily spread to the opposing jaw, pharynx and deep fascial spaces.

Systemic antibiotic therapy is recommended unless infection is quite mild with no associated immunocompromising factors. In well localized *pericoronitis*, local antiseptic lavage and gentle curettage under the flap may be effective. Once the acute inflammation subsides, the offending tooth should be extracted or a wedge of hyperplastic pad tissue could be surgically removed.

Fig. 29.21 Periodontitis has been considered to increase the risk of atherosclerosis, coronary heart disease, respiratory diseases (pneumonia), diabetes mellitus, osteoporosis, and preterm birth.

Fig. 29.22 Images of periodontal abscesses. Swelling around the gingival margin is evident. Spontaneous drainage of pus from periodontal pocket is often seen.

Fig. 29.23 Acute pericoronitis in the mandibular third molar. (a) The flap of gingiva over the partially emerged tooth can trap fluids, debris, bits of food, and bacteria, which are involved in the infection. (b) The erythema and swelling of gingiva and the retromolar pad are evident.

Bacteriology of odontogenic infections

Odontogenic infections are usually polymicrobial, with four to five or even more bacterial species isolated.³⁷ Most bacteria involved are of low virulence, so microbial synergism is believed to play an important role in development of infection.^{72,82}

There are no notable differences in the microbiology of periapical abscesses, periodontal abscesses, and pericoronitis.³⁷ The vast majority of species recovered from odontogenic infections are normal residents of the oral cavity. Although various organisms are detected, certain organisms are more frequently recovered than others (Table 29.19).^{37,72,82–84} These include viridians streptococci, peptostreptococci, and Gram-negative, strictly anaerobic bacilli. These organisms are considered to play a determinative role in the infection process and are regarded as major pathogens. Recent investigations have high-

lighted a predominance of strictly anaerobic bacteria. Strict anaerobes are reported to be recovered in more than 90% of the infections. Gram-negative anaerobic bacilli, including *Prevotella*, *Porphyromonas*, and *Fusobacterium* species are the most frequent isolates from odontogenic infections.^{37,82–84} Commonly recovered *Prevotella* species include *P. intermedia*, *P. nigrescens*, *P. melaninogenica*, *P. oralis*, *P. buccae*, and *P. oris*.⁸⁵ *Porphyromonas* species, especially *P. gingivalis*, are also often recovered from all forms of the disease. *Fusobacterium nucleatum* and its subspecies are the predominant form of fusobacteria involved in odontogenic infections. The involvement of *Tannerella forsythensis* (*Bacteroides forsythus*) and *Treponema* species may be overlooked because they are often not recovered by culture, but nevertheless are frequently detected by molecular analysis.^{82,86}

The predominant streptococcal bacteria belong to the *S. anginosus* group (*S. milleri* group), whilst *S. sanguinis* and *S. salivarius* are rarely recovered.

Table 29.19 Bacteriology of odontogenic infection. Identification of isolates from pus specimen from 87 patients, Kanazawa University Hospital, between September 2001 and March 2005.

Aerobic and facultative bacterial species	Percentage of isolates	Anaerobic bacterial species	Percentage of isolates
Viridans streptococci	6	<i>Prevotella</i> species	34.4
<i>Corynebacterium</i> species	3.1	<i>Fusobacterium</i> species	14.6
<i>Staphylococcus</i> species	2.2	<i>Peptostreptococcus</i> species	13.5
<i>Lactobacillus</i> species	0.7	<i>Porphyromonas</i> species	4.9
<i>Capnocytophaga</i> species	0.4	<i>Veillonella</i> species	2.9
<i>Neisseria</i> species	0.4	<i>Bacteroides</i> species (bile-sensitive)	1.6
Unidentified aerobic Gram-negative bacilli	2.7	<i>Eubacterium</i> species	0.4
		<i>Actinomyces</i> species	0.4
		<i>Bifidobacterium</i> species	0.2
		<i>Propionibacterium</i> species	0.2
		Unidentified anaerobic Gram-negative bacilli	12.2
		Unidentified anaerobic Gram-positive cocci	0.7

Streptococcus mutans is rarely isolated despite being the prime pathogen of dental caries. There is debate over the potential patho-etiological importance of *Staphylococcus aureus*. Although isolation of this organism often arises through contamination of the specimen at the time of sampling or in the laboratory, *S. aureus* may be relevant in the development of infection in some cases.

Most of the major bacterial pathogens are generally susceptible to penicillin (Table 29.20), although some published studies suggest a high prevalence of penicillin-resistant isolates.⁸⁷ However, 30–60% of *Prevotella* isolates exhibit resistance to a wide range of β -lactam antibiotics, including penicillin and even broad-spectrum cephalosporins.^{31,88} This resistance involves bacterial production of β -lactamase.

Pathology of odontogenic infections

Odontogenic infections are opportunistic. Normally, the host defense systems maintain the homeostasis between host and bacteria. However, if the homeostasis is disrupted, bacteria may start to proliferate and invade the tissues. Various local and general factors may be involved in the disruption of homeostasis. The transient decline of host defense activity might trigger the disruption of microbial homeostasis. Acute viral nasopharyngitis (common cold), fatigue, insomnia, and poor appetite often act as triggers. In addition an inadequate use of the root canal file beyond the apex, which creates bleeding or increased exudation into the canal, during endodontic treatment for chronic periapical disease, might provide a stimulus for the overproliferation of microorganisms.

Invasion of pathogens into the tissue causes a rapid and non-specific inflammatory response, which may be expressed as local inflammatory signs, including pain, swelling, redness, heat, and dysfunction, and systemic symptoms, such as general discomfort, fever, and balance disorders. Systemic conditions that compromise the host defense mechanisms, such as diabetes mellitus, and receipt of corticosteroids, anti-cancer agents, and immunosuppressants, increase the likelihood of occurrence of acute infection and risk of extensive progression.

The natural history of progression and clinical features

Bacterial infections of dental origin have a characteristic natural history and clinical features. In acute infection of periapical origin, the periodontal ligament is initially inflamed. In the case of periodontal abscess and pericoronitis, acute inflammation occurs first in the involved gingiva and subsequently in the periodontal ligament. Infection may readily spread to the alveolar bone surrounding the offending tooth and produce considerable pain when exudate and pus are under pressure within bone. Pain also occurs in the gingiva and mucosa around the tooth, usually accompanied by redness, tenderness, and edematous swelling. Intense inflammation of the periodontal ligament results in a slight lift of the tooth from the socket with resultant pain during chewing and increase in the tooth mobility. Regional lymph nodes may be enlarged and tender. An increase in the leukocyte count in the peripheral blood is evident, together with elevation in the percentage of neutrophils. The CRP level is usually elevated even in the early stage of infection. Fever and malaise may appear as systemic signs and symptoms.

The infection spreads equally in all directions but preferentially along the lines of least resistance. In cases of periodontal abscesses, drainage is likely to occur through the periodontal pocket. This may allow spontaneous and constant drainage of purulent material through the periodontal pocket. This is the reason why periodontal abscesses seldom undergo extensive spread. In the case of periapical abscess, the spread is primarily dictated by the thickness of the bone overlying the apex of the tooth (Fig. 29.24). The infection spreads through the cancellous bone and penetrates the thinnest part of the cortical plate. After the infection erodes through the alveolar bone and overlying periosteum, the location where infection appears in the soft tissue depends on the relationship of the perforation of bone to muscle attachments of the maxillary and mandibular bones (Fig. 29.25).

In the case of maxillary teeth, infection commonly erodes through the labiobuccocortical plate (Fig. 29.26 and Table 29.21). If infection perforates through the bone below the attachment of the muscle to maxilla,

Table 29.20 *In vitro* susceptibility of major pathogens of odontogenic infections. University Dental Hospital of Wales, 1999–2003.

	Susceptibility (%)				
	Penicillin	Erythromycin	Tetracycline	Clindamycin	Metronidazole

Fig. 29.24 The modes of infection spread from alveolar bone to the overlying soft tissue through penetrating the cortical plate in the case of the mandibular molar tooth. (a) If the buccal bone overlying the apex of the tooth is thinner than the bone on the lingual aspect of the tooth, infection is likely to erode buccal cortical bone and spread buccally. (b) If the buccal bone overlying the apex of the tooth is thicker than the bone on the lingual aspect of the tooth, infection may go into the lingual soft tissue (sublingual space).

Fig. 29.25 The modes of infection spread to soft tissue after penetrating alveolar bone, when purulent exudate or pus erodes buccal cortical bone. Once the infection has penetrated the alveolar bone, the precise location of abscess formation is determined by the position of the perforation relative to the muscle attachments. (a) If the infection has eroded through the bone superior to the attachment of the buccinator muscle, it will appear as a vestibular abscess. (b) If infection has eroded through the bone inferior to the attachment of the buccinator muscle, it will be expressed as an infection of the buccal space.

vestibular swelling (abscess) will appear (Fig. 29.27). However, in the case of a long maxillary canine, infection will erode through the bone superior to the insertion of the levator anguli oris and will cause a canine space infection. In premolars and molars, if the infection erodes through the bone superior to the insertion

of the buccinator muscle, it may result in a buccal space infection (Fig. 29.28). A palatal swelling (abscess) may occur in the case of a severely inclined incisor (especially lateral incisor) or the palatal root of a molar. As the apices of the second premolar and the first and second molar teeth are located in close

Table 29.21 Possible mode of spread of odontogenic infection.

Involved teeth	Usual direction of spread	Site of localization
Maxillary central incisor	Labial	Labial vestibule
Maxillary lateral incisor	Labial	Labial vestibule
	Palatal	The palate
Maxillary canine	Labial	Labial vestibule or canine space
Maxillary premolars	Buccal	Buccal vestibule or buccal space
	Palatal	The palate
Maxillary molars*	Buccal	Buccal vestibule or buccal space
	Palatal	The palate
Mandibular central and incisor	Lateral	Labial vestibule or submental space
Mandibular canine	Lateral	Labial vestibule
Mandibular premolar	Buccal	Buccal vestibule
Mandibular first molar	Buccal	Buccal vestibule
	Lingual	Sublingual space
Mandibular second molar	Buccal	Buccal vestibule
	Lingual	Sublingual space or submandibular space
Mandibular third molar	Lingual	Submandibular space or pterygomandibular space

* Infection of buccal roots of maxillary molars commonly spreads buccally, whilst the palatal root may be involved in palate abscess.

relation to the floor of the sinus, infection sometimes spreads to the maxillary sinus.

In the mandible, infections of the incisors, canines, and premolars commonly erode through the labio-buccocortical plate of bone and above the associated musculature. Therefore, vestibular abscesses are commonly formed. In contrast, infections of molar teeth can spread either buccally or lingually. Infection from the first molar is likely to perforate buccally, whilst infection of the third molars usually erodes lingually. Infections spreading buccally will produce vestibular abscesses or buccal space abscesses. In the case of infection spreading lingually, the mylohyoid muscle determines if infection erodes to the sublingual or submandibular space.

An early stage of infection commonly takes the form of cellulitis, which is characterized by diffused swelling, no significant localization of pus, and a tendency of extensive spread. The swelling largely results from edema, and the degree of its hardness depends on the intensity of edema. A significant edema may produce a firmer or hardened (indurated) swelling, accompanied by a shiny appearance, warmth, and redness of the skin or mucosal surface. As the amount of interstitial fluid in the soft tissue reduces, swelling becomes softer and reduced.

Fig. 29.26 Infection of the maxillary molar may spread to vestibular site, buccal space, palatal site or the maxillary sinus. Infection of mandibular molar will spread to vestibular site, buccal space, sublingual space or submandibular space.

Fig. 29.27 Vestibular abscess.

However, if the induration involves the cellular infiltrate of inflammation (and not fibrosis), the time required for resolution may be prolonged.

Once infection has peaked, pus may accumulate centrally within the swelling. Pus tends to move under influences of pressure, gravity, local heat, and/or action of muscle layers. When pus reaches an internal or external surface, it can discharge spontaneously. At periodontal disease sites, the periapical infection may drain through the deep periodontal pocket and form a periodontal–endodontic lesion. In general, the symptoms and signs of patients may improve dramatically after the pus has discharged.

Fig. 29.28 Buccal space infection.

Management

The principles of management are presented in the earlier section, Principles of management of bacterial infections. Surgical drainage is the most important part of management. If pus has been drained adequately, clinical signs and symptoms will dramatically improve. Failure of surgical drainage results in further progression of infection or prolonged period for resolution.

Use of systemic antibiotics does contribute to preventing the spread of infection and onset of serious complications, whilst most odontogenic infections are mild and can be managed with surgical procedure alone. An antibiotic regimen is usually determined empirically (Table 29.22). A penicillin class of antibiotic remains the first choice drug for treatment of odontogenic infections due to their suitable antimicrobial activity, low incidence of adverse effects, their bactericidal properties, and cost effectiveness. The actual choice of antibiotic and the dose may differ between countries due to different guidelines in therapeutic management. For example, in the UK and Japan, amoxicillin is recommended because of its better absorption from the gastrointestinal tract and high peak concentration in the serum.⁸⁹ In North America, penicillin V is often preferred, probably due to its narrow spectrum of activity and its cost effectiveness.⁹⁰ Although cephalosporins generally have a broader spectrum of activity compared with penicillin, their antimicrobial activity level against the major pathogens is not notably superior to that of penicillins.³¹ In the case of patients who have possible

Table 29.22 Antibiotics that may be used for treatment of odontogenic infections.

Very effective
Penicillin
Clindamycin
Metronidazole (alone or in combination with a β -lactam)
Cephalosporins
Carbapenems (e.g. imipenem)
β -lactam antibiotics combined with β -lactamase inhibitors (e.g. co-amoxiclav)
Effective
Macrolides (e.g. erythromycin or azithromycin)
Tetracyclines
Quinolones
Less effective
Sulfa drugs
Aminoglycosides

penicillin hypersensitivity, use of erythromycin, clindamycin, and metronidazole is recommended. These agents are also suitable alternatives when the causative bacteria are suspected as being penicillin resistant.

Fascial space infections

Orofacial infection can extensively spread superiorly to the skull base and inferiorly to the diaphragm. The spread of infection is largely determined by location and direction of fasciae. Infection generally spreads through the path of least resistance in subcutaneous connective tissues and along fascial planes, with separation of the layers of fascia. Purulent exudates, including pus and gas, tend to collect at specific locations, forming a space (termed fascial space). Fascial spaces commonly form in loose connective tissue between muscles or skin and bone, and have real and potential paths to communicate with other spaces.^{91,92} The communications between spaces are presented in Fig. 29.29. Infections can progress extensively and rapidly, affecting several spaces. This type of infection is called fascial space infection.

Each fascial space infection produces characteristic clinical signs and symptoms, which are associated with the anatomy. There are vital structures around deep fascial spaces in the head and neck. Involvement of these spaces may result in occurrence of serious complications, such as airway obstruction and mediastinitis. In the past, these infections resulted in a high mortality rate. Although the prognosis has now been much improved due to the establishment of modern therapy, fascial space infection remains a significant health problem with links to fatal complications.

Fig. 29.29 The relation and communication between fascial spaces in oral and maxillofacial regions.

Etiology and microbiology

Fascial space infections can arise from many causes, the principle ones being diseases of the mouth, pharynx, tonsil and salivary glands, and surgical wound and trauma infections. Odontogenic infection is generally the most common cause.

As the majority of fascial space infections begin as odontogenic infections, the causative organisms of both diseases are similar (Table 29.23). The infections usually yield facultative and strictly anaerobic bacteria that reside within the oral cavity.^{93–95} However, in infections involving deep cervical spaces, such as the lateral pharyngeal and retropharyngeal spaces, *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Klebsiella pneumoniae* are often recovered.

Table 29.23 Microorganisms recovered frequently from fascial space infection.

Aerobic and facultative bacterial species	Anaerobic bacterial species
Viridans streptococci	<i>Prevotella</i> species
<i>Staphylococcus aureus</i>	<i>Fusobacterium nucleatum</i>
<i>Streptococcus pyogenes</i>	<i>Peptostreptococcus</i> species
<i>Streptococcus pneumoniae</i>	<i>Veillonella</i> species
<i>Corynebacterium</i> species	<i>Bacteroides</i> species (bile-sensitive)
<i>Escherichia coli</i>	<i>Eubacterium</i> species
<i>Haemophilus influenzae</i>	
<i>Pseudomonas</i> species	

Principles of diagnosis and management

Diagnosis

It should be highlighted that infections of some fascial spaces involve airway obstruction. Therefore confirmation of an adequate airway is the first priority of diagnosis and treatment. It is also necessary to determine if there is indication of other complications, such as sepsis.

Observation and palpation can provide diagnostic information on the involvement of superficial fascial spaces. In contrast, deep fascial spaces have a complex anatomy and are covered with a substantial amount of unaffected superficial soft tissues. As a consequence such infections may be difficult to palpate and to visualize externally, and therefore there is a greater risk of overlooking the involved compartments. Although some clinical findings may offer valuable clues in determining the site and extent of infection, diagnosis should be made with a CT scan and MRI study.

Another important consideration is the host defense level of the patient, because poor host defense is strongly associated with rapid progression and development of serious complications and affects response to the treatment.

Management

Although the principles of management are similar to those for odontogenic infections, a more aggressive attitude is required (Table 29.24). As stated earlier, the first priority is the management of an adequate airway. In emergency situations, tracheostomy or cricothyroidotomy should be performed before any therapeutic measures are attempted. It should be noted that oral or nasal endotracheal intubation can be difficult because of swollen pharyngeal walls and laryngeal displacement, and a failure of instrumentation may result in additional swelling.

Surgical drainage has a critical role in the management of these infections. Early incision may be of great value even when pus has not collected in the abscess, because it may provide a reduction of pres-

Table 29.24 The principles of management for fascial space infections.

The first priority is airway management
Adequate diagnosis using CT scan or MRI
Careful and constant evaluation of patient’s condition
Early incision and drainage even in the case of no apparent evidence of abscess formation
Aggressive antibiotic therapy via intravenous route
Adequate supportive care with hospitalization
Assess and correct any immunocompromising factors and others that may delay recovery

sure in the tissues and allow exploration of undetected abscesses. Therefore the surgeon should not wait for apparent evidence of pus accumulation. However, aggressive surgical intervention may cause injury to vascular and neural structures with resulting sequelae and scarring. Therefore actual treatment will vary depending on circumstances, with consideration of the status of the individual patient and the relative merits of aggressive surgery. Some less severe infections with an absence of any immunocompromising factors may be managed with simple intravenous antibiotics and supportive care (plus extraction of the inciting tooth), therefore avoiding aggressive surgical treatment. In such cases, careful and constant monitoring of the patient is necessary. It should again be highlighted that these infections may progress very rapidly and the clinician should not hesitate to perform surgery if the situation deteriorates.

Surgical drainage

Surgical drainage is the most effective and reliable means of treatment (Table 29.25). A generous incision and aggressive but careful exploration of the involved spaces are required. A secure airway must be established before initiating any surgical procedure, as edema and hematoma associated with surgery may cause additional compromising of the airway. If necessary, a surgical airway should be established. Use of general anesthesia is recommended in cases of extensively spreading or deep infection. A properly and carefully placed incision and blunt dissection with hemostat or finger to avoid surgical injury of important structures are essential. All involved compartments must be opened, and multiple drains should be placed to provide adequate drainage and decompression of the infected area. If an adequate outcome is not obtained, undetected or unexposed abscesses might be involved. Repeat of surgical intervention should then be undertaken without delay.

Antibiotic therapy

Since microbiologic data are necessary to determine each case-specific choice of antibiotic, clinical samples should be obtained whenever possible. Nevertheless, the choice of antibiotic is usually empiric during the first visit of the patient. A penicillin class antibiotic is

the recommended first-choice drug for treatment of fascial space infections (Table 29.26). It should be noted that the diffusion of antibiotic into closed fascial spaces might be limited because of poor vascularity. In addition, the host defense level can often deteriorate even in patients with normal immunity because of fatigue, dehydration, and malnutrition. Therefore a standard dose of antibiotic may prove inadequate. Administration of a high dose (usually maximum) of antibiotic or the use of two or more types of antibiotics in combination that provide a synergistic effect should be considered. Administration of antibiotic through the intravenous route is strongly recommended because it ensures adequate plasma level of the drug. In cases of penicillin allergy, clindamycin and metronidazole may be the best alternatives, although erythromycin is an adequate candidate for mild to moderate infections. If involvement of penicillin-resistant organisms is suspected, metronidazole, clindamycin, co-amoxiclav, and carbapenem may also be recommended. Intravenous antibiotic therapy should continue until resolution of infection is confirmed, and then an additional course of oral antibiotics should be given for an adequate period to prevent recurrence.

Supportive care

The principles of medical supportive care are described in the earlier section, Principles of management of bacterial infections. Constant and careful

Table 29.25 Principles of surgical drainage.

Establish a secure airway before procedure
A generous incision and aggressive exploration of the involved spaces
Properly placed incision and blunt dissection without damage to important structures
Open all involved compartments without overlooking any potential tissue space
Place multiple drains
Should not hesitate to repeat surgical intervention if adequate outcome is not evident

Table 29.26 Instances of suggested antibiotic regimens for fascial space infections.

Antibiotic regimens for less severe cases*	
Penicillin (e.g. penicillin V, amoxicillin)	Maximum dose, orally
Erythromycin	Maximum dose, orally
Clindamycin	Maximum dose, orally
Metronidazole	Maximum dose, orally
Co-amoxiclav	Maximum dose, orally
Penicillin + metronidazole	Maximum dose, orally
Antibiotic regimens for moderate to severe cases	
Penicillin (e.g. penicillin G, ampicillin)	Maximum dose, intravenously
Co-amoxiclav	Maximum dose, intravenously
Ampicillin-sulbactam	Maximum dose, intravenously
Clindamycin	Maximum dose, intravenously
Imipenem	Maximum dose, intravenously
Penicillin + metronidazole	Maximum dose, intravenously
Penicillin + clindamycin	Maximum dose, intravenously
Co-amoxiclav or ampicillin-sulbactam + Clindamycin or metronidazole	Maximum dose, intravenously

* For example, the infection of buccal or canine space in patients who are not immunocompromised.

monitoring of the patient with intervention at the earliest sign of complication, especially a compromised airway, is necessary. Severe cases may require management by appropriate specialists in an intensive care unit.

Patients may have an underlying compromise of their normal immune defenses. Such factors that may delay recovery should be assessed and corrected. Patients usually suffer severe pain, dysphagia (difficulty swallowing), and trismus, and often have a poor appetite due to depression, malaise, and pain. As a result, patients may be exhausted with a degree of dehydration and malnutrition. It should be remembered that infection itself produces a compromised host.

Unless infection is mild with little risk of progression, patients should be hospitalized for intravenous antibiotic therapy, constant monitoring of their condition, adequate pain control, and management of fluid balance and nutrition.

Specific fascial space infections

Anatomy, clinical features, and surgical intervention of facial space infections that may be particularly important for dentists are discussed here. Bacterial infection in the mouth primarily spreads to involve contiguous fascial spaces. These spaces include sublingual, submandibular, submental, buccal, and canine spaces. Although most infections do not extend further, infection occasionally progresses to the posterior fascial spaces, passing through the primary spaces. The masticatory space and deep cervical fascial spaces are of importance for dentists because infection of these spaces can develop into serious conditions.

Sublingual space infection

The sublingual space is defined superiorly by the mucosa in the floor of the mouth and inferiorly by the

Fig. 29.30 Sublingual space infection occurs when odontogenic infection of the mandible perforates the lingual aspect of cortical bone above the attachment of mylohyoid muscle.

mylohyoid muscles (Fig. 29.30). Anterior and lateral borders are the lingual surface of mandibular bone. The sublingual space contains the sublingual gland, submandibular duct, lingual nerve, and sublingual artery and vein.

Odontogenic infection is the most common cause of a sublingual abscess, although sialolith and sublingual gland infection can also be included in the etiology. The mylohyoid muscle separates the sublingual space above from the submandibular space below (Fig. 29.31). This muscle attaches to the lingual surface of the mandible in an obliquely downward line from posterior to anterior. Since the anterior teeth and first molars commonly attach superior to the mylohyoid insertion, sublingual abscesses usually result from an infection arising from the roots of these teeth. As the sublingual space is divided into right and left by only loose connective tissue, sublingual space infections often expand bilaterally.

Infection of the sublingual space produces erythema and swelling of the floor of the mouth, accompanied by pain and tenderness, but creates little or no extraoral swelling. An elevated tongue is an important hallmark of this type of infection and it may result in a difficulty to freely move the tongue. As the sublingual space communicates with the submandibular space in the posterior aspects, infection may readily spread to the latter.

Surgical drainage can be performed through the intraoral approach with an incision of the mucosa, parallel to Wharton's duct (Fig. 29.32). If infection extends to the submandibular space, surgical drainage via a percutaneous approach may be required.

Submandibular space infection

The submandibular space lies between the mylohyoid muscle, superficial fascia, platysma muscle, and the submandibular skin (Fig. 29.33). The contents of this space include the submandibular salivary gland, its duct portions, and the submandibular

Fig. 29.31 The mylohyoid muscle determines if infection erodes to the sublingual or submandibular space. If the infection perforates the lingual cortical surface of mandibular bone above the attachment, the sublingual space will be involved. Conversely, if infection erodes inferior to the mylohyoid line, it will spread to the submandibular space directly.

lymph nodes. The posterior border of the submandibular space communicates with the masticatory spaces and lateral pharyngeal spaces. As discussed earlier, the attachment of the mylohyoid muscle on the lingual surface of mandibular bone determines if odontogenic infection spreads into the submandibular or sublingual space. As the second and third molar roots are commonly below the mylohyoid ridge, infection presenting on the lingual surface tends to enter the submandibular space.

A submandibular space infection produces pain, erythema, and a brawny or soft swelling of the submandibular triangle (the region of the neck immediately beneath the mandibular body) (Fig. 29.34).

Fig. 29.32 For surgical drainage for sublingual abscess, an intraoral incision is employed. As shown in the figure, the incision should be placed in the mucosa of the floor of mouth, parallel to Wharton's duct. The edge of the knife should not be inserted deeply to avoid injury of lingual artery and nerve and duct of submandibular gland. After incision of mucosa, the abscess cavity is encountered by blunt dissection of underlying connective tissues.

Fig. 29.33 Submandibular space infection usually originates from infection of mandibular molar tooth that erodes the lingual cortical surface below the attachment of mylohyoid muscle.

Infection often affects muscles of mastication, resulting in trismus. Infection can spread to involve the masticator and lateral pharyngeal spaces.

Surgical drainage via a transoral approach is usually difficult. Drainage is generally achieved by incision of the skin below and parallel to the mandible, with subsequent blunt dissection to the depths of the space, with attention to avoid any surgical damage to significant structures, including the submandibular gland, the facial artery, and the lingual nerve (Fig. 29.35).

Submental space infection

The submental space exists below the chin. It lies between the submental skin, the anterior bellies of

Fig. 29.34 Submandibular space infection involved in pericoronitis of mandibular third molar. Edematous swelling with erythema is evident in the submandibular region. Due to swelling, the boundary between the mandibular angle and neck becomes indistinct. Extension of swelling to the buccal space is also evident.

Fig. 29.35 Adequate place of incision is at least two fingers' width below the lower border of mandible to minimize the risk of damage to the marginal mandibular branch of the facial nerve. The incision line should be parallel to the lower border of mandible. The platysma muscle will appear following incision of skin and subsequent blunt dissection of subcutaneous tissue. The platysma muscle and underlying fascia are dissected using a finger or hemostat. The abscess cavity may be encountered around the submandibular gland that normally exists under the fascia.

the digastrics muscle, and the mylohyoid muscles (Fig. 29.36). The submental space contains areolar connective tissue and submental lymph nodes. A submental abscess commonly involves an infected mandibular incisor, although infection of cutaneous wounds and anterior mandibular fractures can also be the cause. A submental space infection produces a gross swelling with erythema and warmth in the chin so that the chin may appear to protrude anteriorly. Infection often affects the submandibular spaces. In contrast, as the tight attachment of superficial cervical fasciae to the hyoid bone prevents extension of infection inferiorly to the lower neck, submental infection seldom extends directly to the lower cervical regions.

Percutaneous surgical drainage is an effective approach to management, with an incision placed below the chin, parallel to the lower border of mandible (Fig. 29.37).

Ludwig's angina

The floor of the mouth contains the sublingual space, submandibular space, and submental space, and there is ready communication across the midline through to the opposite site. Due to this anatomy, infection may readily spread from the sites initially involved to most or all of the spaces in the floor of the mouth. This condition is called Ludwig's angina, named after the German physician, Wilhelm Frederick von Ludwig, who described the condition fully in 1836.⁹⁶ Since most cases of Ludwig's angina are of dental origin, bacterial cultures may mirror the oral flora. These infections usually involve viridans streptococci and anaerobes.⁹⁷

Ludwig's angina is characterized by a firm swelling of the floor of the mouth with elevation of the tongue, a relatively spreading cellulitis with no ten-

Fig. 29.37 Surgical drainage for submental abscess is usually performed through a cutaneous incision. A horizontal incision should be placed 1–3 cm below the lower border of the mandible rather than the top of the swelling (abscess) to exploit gravity to encourage drainage.

dency to form abscesses and involvement of bilateral submandibular and sublingual spaces (Fig. 29.38). The majority of infections begin in the submandibular space, often resulting from an infection of a mandibular molar tooth, and then rapidly spread to involve the sublingual space, usually on a bilateral basis. Although the initial symptoms are unilateral, they will progress to involve both sides. The submandibular and submental regions become tense, swollen, and tender. There is increasing neck rigidity, trismus, odynophagia (painful swallowing), and drooling. The floor of the mouth will become tense and indu-

Fig. 29.36 Submental space infection caused by periapical abscess in the mandibular incisor.

Fig. 29.38 (a) Ludwig's angina involved in odontogenic infection. A swelling with redness started in the right submandible and then extended to involve the floor of mouth, chin and opposite site. (b) Vigorous incision is required. Photographs were obtained from Dr T. Aoki (Tokai University).

rated with extensive mucosal swelling. Intense pain is usually present, but fluctuance is unusual. The tongue is pushed superiorly and its movements become stiff. The patient can develop a toxic condition, with high fever, tachycardia, and malaise often observed. As the swelling progresses, there is increasing encroachment upon the airway, resulting from elevation of the tongue and extension to the lateral pharyngeal space. It should be noted that progression from the onset of symptoms to respiratory obstruction often occurs within 12–24 hours.

The infection may spread to involve posterior fascial spaces, in particular the lateral pharyngeal space. Ludwig's angina has historically been associated with a high mortality rate, primarily due to inadequate diagnosis and management of airway obstruction. Although the prognosis has improved, Ludwig's angina remains a serious and life-threatening disease.

With regard to treatment, special attention must be given to maintenance of the airway. Early and vigorous incision and aggressive opening of all involved spaces are recommended to provide decompression of the area involved. Drainage through generous incision on the skin in the submandibular and submental regions is required. Although the length of the cutaneous incision may be variable, incision generally crosses to the submandibular region bilaterally. In addition to extraoral drainage, transoral drainage should be undertaken if instruments can be inserted into the oral cavity.

Buccal space infections

The buccal space occupies the portion of the subcutaneous space between the facial skin and the buccinator muscle. It contains the buccal fat pad, parotid duct and the facial artery. Common sources of buccal abscess are through involvement of the maxillary or mandibular premolar and molar teeth (Fig. 29.39).

Involvement of the buccal space usually results in a remarkable cheek swelling in the region between the zygomatic arch and the inferior border of mandible (Fig. 29.40). Abscesses may be palpable (fluctuance) intraorally and/or subcutaneously. Buccal

Fig. 29.39 Buccal abscess results from entry of purulent materials from odontogenic infections eroding the cortical plate superiorly to the maxillary attachment of the buccinator muscle or inferiorly to the mandibular origin of the muscle. (Illustration was redrawn with permission from Cummings CW, *et al.*, editors, *Otolaryngology: Head and Neck Surgery*, vol 2. St Louis, MO: Mosby, 1986.⁹⁸ Copyright © 1986 Elsevier.)

infections can extend into the periorbital and masticator spaces. Drainage is usually achieved by cutaneous incision.

Canine space infections

The canine space is a potential space that exists between the levator anguli oris and the levator labii superioris muscles. If the infection perforates the lateral cortex of the maxillary bone superior to the attachment of either of these muscles of the upper lip, the canine space is potentially involved. It is only the canine tooth that has a sufficiently long root through which infection may enter the canine space. Therefore canine space infections primarily result from infections of the maxillary canine tooth.

Fig. 29.40 Two cases of buccal abscess.

When the canine space is infected, there is a swelling of the anterior face that may obliterate the nasolabial fold. Canine space infection may also cause edematous swelling in the eyelids (Fig. 29.41). In later stages, infections may spread to involve the orbit.

Drainage through an intraoral approach with incision high in the maxillary labial vestibule is recommended. Although drainage with extraoral incision is also an option, it may result in scarring.

Infections of the masticatory spaces

Masticatory spaces is a clinical term used to describe the entire area of the mandible and muscles of mastication. It contains the masseter muscle, the ramus and posterior part of the mandibular body, the tendinous insertion of the temporalis muscle, the medial and lateral pterygoid muscles, and the inferior alveolar nerve and vessels. The spaces comprise three major subgroups, the temporal space, the pterygo-mandibular space, and the submasseteric space (Fig. 29.42). Since these spaces communicate with

one another, once one portion becomes infected the others may also be affected. Moreover, these spaces communicate with the buccal, submandibular, and lateral pharyngeal spaces so that infection of the masticatory spaces may spread to these spaces and the converse can also occur.

Trismus is commonly seen and might be a relatively long-term sequela. Due to significant trismus and dysphagia, the fluid balance and nutrition level of the patient often deteriorates.

Since severe trismus hinders the insertion of surgical instruments and prevents intraoral surgical approach, drainage usually requires cutaneous incision in the submandibular region and subsequent dissection of underlying soft tissue to the depth of the abscess cavity (Fig. 29.43).

Submasseteric space infection

The submasseteric space lies between the lateral aspect of the mandible and the medial boundary of the masseter muscle. The space is commonly affected by infection of the mandibular molar, especially the

Fig. 29.41 Two cases of canine space infection involved in periapical abscess in the maxillary canine. The swelling of anterior maxilla with erythema and edema of the eyelid is evident.

Fig. 29.42 Submasseteric space, temporal space, and pterygomandibular spaces lie around the mandibular ramus. Infection of the mandibular molars may spread to these spaces. The spaces are surrounded by masseter muscle, lateral and medial pterygoid muscles, temporal muscle, and skull. (Right illustration was redrawn with permission from Cummings CW, *et al.*, editors, *Otolaryngology: Head and Neck Surgery*, vol 2. St Louis, MO: Mosby, 1986.⁹⁸ Copyright © 1986 Elsevier.)

Fig. 29.43 Surgical drainage for submasseteric or pterygomandibular abscess involves cutaneous incision. Similar to the case of submandibular abscess, the incision should be placed at least two fingers' width below the lower border of mandible and subcutaneous tissue is dissected up to the inferior surface of the mandibular bone. When the mandibular bone is encountered, the attachment of masseter muscle or medial pterygoid muscle to the bone will be palpated. In the case of submasseteric abscess, once a part of attachment of masseter muscle to the mandible is exfoliated, the abscess cavity may be encountered. In the case of pterygomandibular abscess, the abscess cavity is explored through partial exfoliation of pterygoid muscle from the bone. Illustration was redrawn with permission from Kitano S, *et al.*, editors, *Korekarano Koku kansensho*, 1st edn. Tokyo: Gakken Shoin, 1993.⁶

third molar, but buccal space infection and fracture infection in the mandibular angle may also be involved. A submasseteric abscess produces pain, swelling in the area overlying the angle of jaw and ramus of the mandible, and trismus.

Pterygomandibular space infection

The pterygomandibular space exists between the mandibular ramus and the medial pterygoid muscle. The etiology of a pterygomandibular abscess is often infection of the sublingual and submandibular spaces, periocoronitis, and postextraction infection of mandibular third molar. It is the pterygomandibular space where a local anesthetic solution is injected for the inferior alveolar nerve block. Contamination following needle injection is therefore also a common cause of this infection. Infection of only the pterygomandibular space induces little or no facial swelling whilst an inflammation of the median pterygoid muscle results in significant trismus. The hallmark of this abscess is trismus without extraoral swelling. The infection usually affects the anterior tonsillar pillar and uvula. Sore throat and dysphagia are usual complaints of the patient. The deviation of the uvula to the opposite site may be observed if trismus is not severe.

Infection of the pterygomandibular space can spread to the lateral pharyngeal space. It is therefore necessary to determine whether the lateral pharyngeal space is also affected.

Temporal space infection

The temporal space is posterior and superior to the submasseteric and pterygomandibular spaces (Fig. 29.44). Temporal space infection may involve swelling in the temporal area that is superior to the zygomatic arch and posterior to the lateral orbital rim.

The temporal space can roughly be divided into two portions by the temporalis muscle: superficial and deep. The superficial temporal space lies between the temporal fascia and the temporalis muscle, and communicates with the submasseteric space. The extension of a buccal space infection can result in superficial temporal space infection. The deep temporal space is surrounded by the temporalis muscle, temporal bone, the skull base, and the lateral pterygoid muscle. Common etiologies of a temporal space infection involve extension of a buccal abscess, infection of maxillary and mandibular third molar, contaminated surgical wound of temporomandibular joint surgery, and arthroscopy.

Cervical fascial space infections

A deep neck infection (abscess) is synonymous with cervical fascial space infection. Despite being quite rare, oral bacterial infections can secondarily induce abscesses in the deep fascial spaces in the neck. Such infections are serious because of the propensity of dissemination hematogenously and contiguously along the fascial planes to involve the mediastinum, pleuropulmonary spaces, and other vital structures. Lateral pharyngeal and retropharyngeal spaces are most commonly involved, and in such circumstances an immediate life-threatening condition occurs through possible airway obstruction (Fig. 29.45).

The lateral pharyngeal space receives purulent material from the fascial spaces around the mandible and the floor of the mouth. Common sources of lateral pharyngeal space infection are from submandibular abscesses and the masticatory spaces. In a typical case, odontogenic infection of the mandible spreads

Fig. 29.44 CT scan demonstrating an abscess formation in the temporal space.

to the submandibular spaces and then extends to the lateral pharyngeal space through the pterygomandibular space. Therefore clinicians should determine whether the lateral pharyngeal space is involved during treatment of fascial space infection in the mandibular area or floor of the mouth.

CT scanning is the gold standard in the evaluation of cervical fascial space infections, as it may visualize the location, boundaries, and relation of the infection to the surrounding neurovascular structures. It is also effective in evaluating the degree of airway obstruction. The presence of gas in the affected soft tissue is often seen on CT scans. This sign strongly suggests the involvement of a necrotizing infectious form that requires immediate attention and aggressive therapy.

Special attention needs to be given to possible damage of vital structures during surgical intervention. Also, considerable hemorrhaging from blood capillaries in inflamed tissues can occur. As a consequence of these potential complications skilled specialists should be involved in the treatment of these infections. However, dentists should understand their clinical features and have sufficient knowledge for diagnosis.

Lateral pharyngeal space infection

The lateral pharyngeal (parapharyngeal) space extends from the base of the skull inferiorly to the level of the hyoid bone. The space contains the medial portion of the carotid sheath, internal carotid artery, internal jugular vein, cranial nerves IX, X, XI and XII, and the cervical sympathetic trunk (Fig. 29.46).^{98,99} There is potential communication with the retropharyngeal space.

Lateral pharyngeal infection causes medial displacement of the lateral pharyngeal wall and tonsil and the deviation of the uvula to the opposite side due to swelling. Trismus is caused by inflammation of the pterygoid muscles, and dysphagia occurs as a result of inflammation of the pharynx. The lateral aspect of the neck is also often swollen. Inflammation of the paraspinal muscles may result in torticollis with a resulting limitation of neck movement. Patients usually have a high temperature and become quite sick.

Fig. 29.45 Cervical fascial space infections. (a) Extensive swelling and redness in the neck and chest are evident. (b) CT scan demonstrates compromise of airway and the presence of gas in affected soft tissue, suggesting involvement of anaerobic bacteria. Photographs were obtained from Dr T. Aoki (Tokai University).

Fig. 29.46 Anatomy of lateral pharyngeal spaces.

It is important to recognize that infection has a potential to cause an airway obstruction. Other possible complications include thrombosis of the internal jugular vein, erosion of the carotid artery or its branches, neural defects, Horner syndrome from involvement of the cervical sympathetic chain, and meningitis resulting from extension of infection to the pterygopalatine fossa and skull base. Mediastinitis could occur as infections spread to the mediastinum through the connective tissue around the carotid sheath or via the retropharyngeal space.

Although drainage can be accomplished by either or both of the transoral and extraoral approaches, an extraoral approach may provide more adequate and reliable entry to the lateral pharyngeal space (Fig. 29.47). Attention is required to avoid injury to neurovascular structures.

Retropharyngeal space infection

The retropharyngeal space lies between the buccopharyngeal fascia (covering the posterior pharynx and esophagus) and the alar fascia (a division of the deep layer of deep cervical fascia), and occupies the space posterior to the pharynx and esophagus (Fig. 29.48). It extends from the skull base to the level of the fourth thoracic vertebra, where the above-mentioned layers fuse.

Infection may enter this space directly, as with traumatic perforations of the posterior pharyngeal wall or esophagus, or indirectly from the lateral pharyngeal space.

Fig. 29.47 Extraoral approach may provide adequate entry to the lateral pharyngeal space. Incision is placed on the skin over the anterior edge of the sternocleidomastoid muscle.

Fig. 29.48 Anatomy of retropharyngeal space and danger space. These spaces are close to the mediastinum and therefore infection of these spaces might spread to involve the mediastinum. (Illustration was redrawn with permission from Cummings CW, *et al.*, editors, *Otolaryngology: Head and Neck Surgery*, vol 2. St Louis, MO: Mosby, 1986.⁹⁸ Copyright © 1986 Elsevier.)

The common clinical findings of this infection include high fever, severe throat pain, dysphagia, and limited neck mobility. In extreme cases there may be breathing difficulty, stridor or tachypnea. Whilst lateral neck radiographs demonstrate a widening of the retropharyngeal soft tissues, a CT scan provides a more reliable diagnostic indicator.

Infection in the retropharyngeal space can spread into the mediastinum directly or via the “danger space”, causing mediastinitis. Moreover, it can cause airway obstruction and rupture of an abscess with subsequent aspiration of pus into the chest, which can lead to acute respiratory failure. Clinicians must remember that there is a significant risk of aspiration during intubation or intraoral incision due to injury to the pharyngeal wall and subsequent rupture of the abscess, so prudent and careful procedure is necessary. Needle aspiration preceding intraoral incision and drainage is effective in reducing the risk of pus entering the chest during the procedure.

Danger space

The “danger space” lies posterior to the retropharyngeal space between the alar and prevertebral fascias, and extends from the skull base down into the posterior mediastinum to the level of the diaphragm. The danger lies in the tendency for infections to spread inferiorly through the space and into the thorax because the loose areolar contents offer little resistance.⁹⁹ Danger space infection results in serious complications including mediastinitis, pleural empyema (pyothorax), and sepsis.

Gas gangrene and necrotizing fasciitis

Severe cervical space infections usually take a necrotizing infectious form. Cervical gas gangrene and necrotizing fasciitis may be used to describe these or overlapping conditions.^{100,101} Whereas a severe cervical space infection only relates to the location of the infection, gas gangrene describes the particular involvement of gas-producing bacteria. Necrotizing fasciitis is used to describe an inflammatory process dominated by tissue necrosis which is spreading rapidly along the fascia.

Gas gangrene in other body sites usually involves *Clostridium* species and necrotizing fasciitis in its classical form is caused by Group A β -haemolytic streptococci.⁹ However, in cervical space infections, non-*Clostridium* anaerobic bacteria, including *Prevotella*, *Fusobacterium*, and peptostreptococci, are

primarily involved and recovery of *Clostridium* species is very rare.

As with other less severe maxillofacial infections, common etiologies include traumatic or surgical wound infections (surgical site infections) and odontogenic infections. Many of these primarily involve the submandibular or the masticator space, and subsequently spread to the lateral pharyngeal or retropharyngeal spaces through the fascial plane with extensive destruction of tissues (Fig. 29.49). There is the potential for spreading downwards into the mediastinum, possibly leading to mediastinitis, pericarditis, lung infection, and sepsis. The infection may spread upwards to the skull base and to the meninges. Another scenario is the spreading of the infection via the blood vessels giving rise to suppurative thrombophlebitis, development of sepsis or disseminated intravascular coagulation.

Pre-existing immunosuppressive conditions, especially uncontrolled diabetes and alcohol abuse, are important predisposing factors, although the infections do occasionally affect otherwise healthy individuals.

Diagnosis is made based on clinical features, imaging study, operative findings, and the patient's progress. An imaging picture of gas formation may be an important diagnostic sign (Fig. 29.50). CT and MRI scans are the most useful imaging methods for diagnosis. It is important, however, that the clinician does not wait for apparent evidence from the imaging study since delayed treatment can lead to fatality. Presumptive surgery should be advocated and diagnosis should be made with surgical inspection.

Management consists of surgery, administration of antibiotics, and supportive medical care. In particular, extensive tissue debridement is most important. Resected tissue should be sent for microbiology culture and any recovered bacteria tested for their sensitivity to antibiotics. The wounds should be sufficiently washed and be left open. Repeated surgical intervention should be carried out without hesitation if deemed necessary. After wound healing, a skin graft may be required.

Administration of a high-dose and broad-spectrum antibiotic via the intravenous route is a

Fig. 29.50 CT scan revealing gas formation in the affected tissue.

necessity. Adequate antibiotics as empirical choices include penicillin, broad-spectrum cephalosporin, imipenem, clindamycin, and metronidazole. To enhance the antimicrobial spectrum and activity, the use of more than one antibiotic is generally recommended. The antibiotic regimen should be modified on the basis of culture and sensitivity results. Hyperbaric oxygen (HBO) therapy is advocated as an adjunctive treatment, although the effect of HBO on patient mortality rate has yet to be proven.

Shock and multi-organ failure are relatively common as is the occurrence of a compromised airway. Resuscitation and general supportive measures are vital and most patients require monitoring in an intensive care unit.

Osteomyelitis of the jaw

Osteomyelitis is defined as an inflammation of bone marrow.³ However, in almost all cases, infection extends to involve the cortical bone and the periosteum of the affected area. Although this disease occurs much less commonly today than in the past, largely due to the widespread use of antibiotics, it remains an intractable disease and can induce serious cosmetic and functional sequelae.

Osteomyelitis of the jaw may be roughly divided into suppurative and non-suppurative, based on clinical features. Although there are several rare forms of the disease, such as syphilitic, tuberculous, and viral osteomyelitis, this section only discusses the relatively common types. Osteoradionecrosis and

bisphosphonate-associated osteonecrosis are also included in the discussion.

Suppurative osteomyelitis of the jaw

Suppurative osteomyelitis is the dominant form of the disease, which is primarily characterized by the production of pus and necrosis of bony tissues. Suppurative osteomyelitis includes two distinct clinical forms, acute and chronic. Acute osteomyelitis presents a clinical picture of an acute infection which usually includes systemic effects. In contrast, chronic osteomyelitis induces minimal systemic upset. Chronic suppurative osteomyelitis may be divided into two subforms, a primary chronic form that manifests with no acute episode and a secondary chronic form, which involves a prolonged inflammatory process.

Etiology

Odontogenic infection is the most common cause of osteomyelitis of the jaw. Additional etiologies include peri-implantitis, infected cyst or tumor, and surgical wound or trauma infection. Hematogenous seeding of bacteria from other body sites is very rare.

Pathogenesis

Inflammation triggered by bacterial invasion into the marrow space induces a compromised microcirculation and increased pressure in the intramedullary site. This may result in vascular collapse, venous stasis and ischemia, and eventually lead to bony necrosis. As ischemic and necrotic bony tissues do not have a sufficient blood supply, host defense mechanisms may not be able to cope effectively with bacterial invasion and proliferation. Multiplication of bacteria and the resultant inflammation induce further necrosis of surrounding bony tissues, resulting in extensive spread of infection.

The blood supply in the bone, the effectiveness of host defense mechanisms, and the virulence of the pathogens are the prime factors involved in the onset, severity, and persistence of osteomyelitis. In particular, restriction of the circulatory system in the bone is a critical factor. In such circumstances, the mandibular cancellous bone is more likely to become ischemic and more sensitive to infection compared with the maxillary bone. This is because the blood supply to the mandibular bone from its regional artery is less oxygenated compared to the blood supplying the maxilla. Furthermore, the dense overlying cortical bone of the mandible prevents penetration of periosteal blood vessels. Hence the body of the mandible is the most common site for disease and osteomyelitis at this site tends to be refractory.

Bone with chronically impaired blood flow and degenerated or fibrous marrow is sensitive to infection. Fibrous bone dysplasia, previous radiation

exposure of the bone, osteoporosis, osteopetrosis, Paget's disease, and the presence of bone tumors are all predisposing factors of osteomyelitis. Osteomyelitis in bone with these factors is usually intractable. As with other forms of infection, osteomyelitis is more likely to become established in immunocompromised patients.

Microbiology

The microbiology of osteomyelitis of the jaw is similar to that of odontogenic infections which is not surprising as the majority of osteomyelitis cases originate from odontogenic infections. Viridans streptococci and strict anaerobes such as *Prevotella*, *Fusobacterium*, and *Peptostreptococcus* species are the predominant isolates.^{103,104} It should be noted that osteomyelitis sometimes involves pathogens that are uncommonly recovered from odontogenic infection, such as *Staphylococcus aureus*.

The stages of disease and clinical features

As the vast majority of osteomyelitis occurs in the mandible, the progression from the acute to the chronic stage of mandibular osteomyelitis is primarily discussed here.

Acute stage

Acute suppurative osteomyelitis is a process that occurs shortly after the predisposing event. The initial phase is characterized by deep and intense pain, high intermittent fever (38–40°C), and an identifiable causative tooth. Other systemic symptoms include chills, malaise, headache, and a decreased appetite. At this juncture, teeth have not yet become loose. Swelling is minimal and fistulae are absent. Infection is localized only at the intramedullary site and adequate treatment at this phase may prevent further progression.

With the spread of infection, systemic toxic symptoms become more severe and sepsis might occur. Blood examination demonstrates a range of leukocytosis with a left shift and an elevated CRP level. Regional lymph nodes become enlarged and tender. Purulent exudate and pus erode the cortical bone and periosteum. As a result, facial or submandibular cellulitis with extensive firm swelling, warmth, and erythema is evident. If the masticatory muscle is affected,

trismus may occur. A range of cancellous bone is involved and multiple teeth adjacent to the infection source begin to loosen. A throbbing pain in the jaw, severe tenderness, and a feeling of extrusion of teeth occur. Teeth anterior to the causative tooth become highly sensitive to mastication and the percussion test. As infection affects the inferior alveolar nerve, areas of mucosa supplied by the trigeminal nerve, such as the lower lip and gingiva, become numb (this is called Vincent's symptom). Subsequently, pus discharge from the gingival sulcus, multiple mucosal fistulas, and cutaneous fistulae, become apparent. Since damaged bony tissues are not yet radiographically detectable, there is little or no radiographical change in the involved area. The disease will either resolve or progress to the more chronic stage, depending on treatment.

Subacute and chronic stage

The acute stage usually continues for 1–2 weeks and, if osteomyelitis is neglected or does not respond to treatment, the disease will develop into a subacute and chronic stage. However, some cases primarily have a chronic form of osteomyelitis, without an acute episode.

In the chronic stage, the body temperature falls into the normal range and most subjective symptoms disappear or become minimal. Teeth in the affected area show a range of mobility and are sensitive to palpation and percussion. Swelling becomes localized and multiple subperiosteal abscesses are usually evident.

The appearance of bony destruction ("moth-eaten" appearance) and a fragment of necrotic bone, (sequestrum) can be confirmed using a plain radiograph (Fig. 29.51). A sequestrum will subsequently separate from living bone. A layer of new bone may form around the necrotic bone, and this is called an involucrum. Portions of osteosclerosis relating to a hyper-inflammatory reaction may be found in the affected area.

In some cases, sequestra are resorbed completely in granulation tissue or are spontaneously expelled through the mucosa or skin, and in these instances are removable through less invasive surgical procedures. In such cases, full resolution of the infection is possible. In contrast, cases can arise where the necrotic bone persists for long periods. In extreme cases,

Fig. 29.51 (a) A panoramic radiograph of chronic suppurative osteomyelitis resulting from postextraction infection of the mandibular molar. (b) In a magnified view of the affected area, a sequestrum with a moth-eaten appearance is observed.

pathological fractures occur due to either a significant volume of bone loss from sequestration or because of reduced bone strength (Fig. 29.52).

Maxillary osteomyelitis

For anatomic reasons, maxillary osteomyelitis is uncommon and usually not aggressive. It tends to become localized in a short period, forming subperiosteal abscesses with a limited size of sequestrum. In contrast with adult cases, osteomyelitis in infants commonly occurs in the maxilla and tends to be severe (this is discussed later).

Diagnosis

Imaging

Conventional plain radiographs

Since radiographic bone imaging can generally detect bony lesions that have lost approximately 30–50% of the calcified constituent,¹⁰⁴ radiographic change becomes detectable 1–3 weeks after the onset of acute osteomyelitis. Consequently conventional radio-

Fig. 29.52 A pathological fracture of the mandible involved in severe chronic suppurative osteomyelitis.

graphs provide little information on the status and extent of infection, although they may be of value to assess the likely cause.

Once osteomyelitis has developed sufficiently, characteristic features will be seen. Affected bone has an increased radiolucency, which may be uniform in its pattern or patchy, with a moth-eaten appearance. Sequestra may be seen as the radiopaque areas like “islands of bone”. There may be an area of increased radiodensity surrounding the area of radiolucency as a result of an increase in bone production associated with the inflammatory reaction.

CT and MRI

Bony change may be detected earlier with a CT scan than with conventional radiographs, although CT may not be an effective diagnostic tool for the very early phase of osteomyelitis. Increased attenuation in the medullary cavity, destruction of cortical bone, proliferation of bony tissue, and formation of sequestra may be observed. A CT scan is particularly useful in visualizing the actual extent of the lesion.

MRI has been reported to be sensitive for the early detection of osteomyelitis, although it lacks specificity on the diagnosis. As the bone marrow is replaced by fluid and inflammatory cells, infected areas can be seen as regions of reduced signal intensity on T1-weighted images (Fig. 29.53) and as regions of increased signal intensity on T2-weighted images.

Radionuclide scans

Radionuclide scanning provides a diagnostic modality superior to conventional imaging techniques for acute osteomyelitis. Technetium and gallium bone scans are commonly used. In technetium bone scans, the lesion is detected by using the characteristics of ^{99m}technetium ions, which accumulate at bony tissue where there is significant osteoblastic or osteoclastic activity. Gallium scan images can depict the lesion

Fig. 29.53 A panoramic radiograph and MRI of chronic suppurative osteomyelitis in the mandible of the same patient. (a) The panoramic radiograph shows an osteomyelitis lesion ranging from the mandibular body to part of the ramus. (b) MRI (T1-weighted image) demonstrates a reduced signal intensity in the whole mandibular ramus, suggesting infection that erodes extensively in the mandibular ramus. Infection also affects the surrounding soft tissues.

since ⁶⁷Ga ions tend to accumulate at inflammatory sites.

Diagnostic principles

Diagnosis of acute osteomyelitis is generally based on the history, clinical findings, such as deep intense pain, paresthesia of the inferior alveolar nerve or mental nerve, and fever, and results of blood examination.

In chronic osteomyelitis, bony destruction can be confirmed with plain radiographs. Therefore, diagnosis is usually made based on a combination of medical history, clinical findings, and radiographic appearance. Differentiation from bone tumors and fibrous bone dysplasia is required as these often exhibit similar radiographic appearances.

Treatment

Treatment consists of antibiotics, surgery, and supportive care. Acute suppurative osteomyelitis of jaws is primarily managed by antibiotic therapy. Adequate antibiotic therapy is started during the early stage of the infection and surgical removal of the cause may provide complete resolution of the disease without the subsequent chronic stage. In the case of chronic osteomyelitis, surgery plays a key role in the management.

Antibiotic therapy

Osteomyelitis commonly occurs in bones with an inadequate blood supply or in immunocompromised patients. Therefore, use of high doses of antibiotics is generally recommended. Moreover, as an adequate antibiotic level in the serum must be maintained, the antibiotics should be administered intravenously. In general, the recommended antibiotics belong to the penicillin class because of their high activity against the bacteria commonly involved. Clindamycin and metronidazole can be excellent alternatives for patients who are hypersensitive to penicillin. Suggestions for an empirically selected antibiotic regimen are presented in Table 29.27. It is worth noting that because osteomyelitis can involve a variety of bacteria, clinical specimens should be obtained for microbiologic examination and, whenever possible, the chosen antibiotic regimen should be based on these findings.

In the case of acute osteomyelitis, the course of intravenous therapy should continue until clinical signs have completely disappeared, and an additional course of oral antibiotic should then be taken to ensure complete eradication of the infection, although the duration of the course will vary depending on the case.

In chronic osteomyelitis, intravenous antibiotic administration is recommended after surgery until evidence of wound sealing is seen. This is undertaken even in instances where there are no signs of infection recurrence. Additional courses of oral antibiotics to

Table 29.27 Suggested antibiotic regimens for suppurative osteomyelitis.

Antibiotic for initial therapy	
(1) Penicillin (e.g. penicillin G or ampicillin)	Maximum dose, intravenously
(2) Clindamycin	Maximum dose, intravenously
(3) Co-amoxiclav or ampicillin–sulbactam	Maximum dose, intravenously
(4) Imipenem	Maximum dose, intravenously
(5) Penicillin + metronidazole or clindamycin	Maximum dose, intravenously
After clinical signs have resolved (in the case of acute osteomyelitis) or initial healing of surgical wound is confirmed (in the case of chronic osteomyelitis), switch to one of the following regimens for an additional 4–6 weeks	
(1) Penicillin (penicillin V or amoxicillin)	Standard dose, orally
(2) Cephalexin	Standard dose, orally
(3) Erythromycin	Standard dose, orally

minimize the risk of recurrence following intravenous therapy are often advocated, although the duration of treatment may vary with each case. It should be noted that chronic osteomyelitis is difficult to manage with antibiotic therapy alone. If treatment failure is suspected (e.g. an uncommon persistence of postoperative pain, pus discharge, and inadequate wound healing despite performing aggressive antibiotic therapy in the postoperative period), a change of the antibiotic regimen could be of value, but commonly reoperation is required.

Surgery

The role of surgical treatment in acute suppurative osteomyelitis is generally limited. Loose teeth, sequestra, and involvement of a readily accessible foreign body should be surgically removed as soon as possible. In cases where there is extensive pain, trephination techniques can be employed for drainage of pus.

In contrast, surgery is important in the treatment of chronic osteomyelitis. In these infections, there are large areas of ischemic and necrotic bone that may prevent the effect of treatment and interfere with the natural healing mechanisms. The purposes of surgery are: (1) to improve the blood supply in the involved area thereby allowing adequate penetration of antibiotic; and (2) to maximize the host defense mechanisms and self-healing ability. Sequestra, non-vital bone, involved foreign bodies, inflammatory granulation tissue, sclerotic bone resulting from long inflammatory reaction, and any devitalized tissues with compromised vascularity must be thoroughly removed in surgery. During the operation, it may be difficult to distinguish healthy and devitalized

bony tissues and to determine the surgical margin. Generally, bone should be removed until vital bleeding areas are encountered in all directions. The wound is irrigated with copious amounts of saline solution to reduce contamination. The following surgical procedures are commonly used:

- *Sequestrectomy.* In some cases, once full formation of sequestrum has been confirmed, removal can be performed by simple incision and small surgical trauma.
- *Saucerization and decortication.* Both saucerization and decortication involve surgical removal of infected bone marrow and overlying cortical bone. However, the techniques are distinct:
 - Saucerization involves the surgical excavation of bony tissue to form a shallow depression to facilitate drainage from infected areas with improvement of blood supply to bone and to prevent formation of dead space (Fig. 29.54). After the cortical bone is unroofed to expose the involved medullary cavity, thorough debride-

Fig. 29.54 Saucerization generally consists of the following steps. (a) After incision, the buccal mucoperiosteal flap is reflected to expose the infected bone. Extensive tissue reflection is unnecessary to preserve blood supply. Then, loose teeth, pus, sequestrum, necrotic tissue and granulation in the bone marrow and cancellous bone are removed with sharp curettes. The procedure should be performed carefully to avoid damage to the inferior alveolar nerve and vessel. (b, c) Bone in affected areas is reduced using burs or rongeurs until vital bleeding of the area is encountered at all margins. Any sharp bony portion and undercut portion are arranged using burs and bone files to produce a saucer-like depression of the bone. (d) After the surgical area is thoroughly irrigated with copious amounts of saline solution, the buccal flap is trimmed and a medicated gauze pack (for example, gauze covered with iodiform or antibiotic ointment) is inserted for hemostasis and to maintain the flap in a retracted position. The pack is placed firmly and slightly overfilling the defect but should not put pressure on the defect. If necessary, several sutures are tied over the pack to maintain its position. The sutures should be removed 5–7 days after surgery. As healing of the surgical wound proceeds, the bony defect is replaced by granulation tissue and therefore the size of defect will reduce. The gauze pack should be replaced every 7–10 days until signs of initial healing, such as presence of an epithelialized surface on the bed of granulation tissue, are confirmed.

ment is performed and then the margin of bony defect is arranged to eliminate sharp edges and undercut portions. The wound is closed either by primary or secondary intention. However, as primary closure of the wound involves a high risk of recurrence or wound infection, leaving the wound open for healing should be considered. This wound treatment is effective in the prevention of the recurrence of osteomyelitis and also in reducing the risk of wound infection because it decompresses the bone from exudate or pus and may allow subsequent exfoliation of necrotic tissues. Dressings for the wound should be changed frequently after surgery. If therapy is successful, the wound will be closed by regeneration of connective tissue without any wound-healing problems.

- Decortication is a surgical procedure that aims to encourage an increased blood supply to bone marrow in the infected area from the blood vessels of buccal periosteum. This is achieved through surgical removal of the buccal bony cortex and subsequent creation of direct contact of exposed bone marrow with the mucoperiosteal flap. The lateral and inferior cortex plates are removed to form a window after the mucoperiosteal flap is elevated (Fig. 29.55). Pus,

sequestrum, necrotic tissue, and granulation that exist under the cortical bone should be carefully removed and the surgical area is then irrigated. After irrigation and placement of suction drains, primary closure of the wound is performed.

- *Resection and reconstruction of the jaw.* Resection of infected areas and immediate or delayed reconstruction may be considered if an involved area is extremely extensive or less aggressive surgical procedures have failed.

Supportive care

Patients should be hospitalized for any aggressive surgery, and provided with intravenous antibiotic therapy and managed for correct fluid balance and nutrition. As mentioned previously, the patient is likely to have an underlying compromise of their host defenses. The factors that may delay recovery should be assessed and corrected.

Hyperbaric oxygen therapy

HBO therapy may be available in conjunction with surgery. It is a mode of treatment in which a patient breathes 100% oxygen at a pressure greater than normal atmospheric pressure. Because of the increased oxygen tension, large amounts of oxygen dissolve in

Fig. 29.55 Decortication generally consists of the following steps. (a) After the buccal mucoperiosteal flap is reflected to the inferior border of mandible, the lateral cortical plate is removed to form a window. If loose teeth are presented, they should be removed. (b) The lateral cortical plate and a portion of the inferior cortical plate are then removed and debridement of the bone bed should be performed thoroughly. Any bleeding areas should be included in the margin of the uninvolved area. (c) The flap is primarily closed, and use of a pressure bandage or insertion of a tube drain is employed to eliminate dead space. An additional blood supply to the exposed bony tissue from the periosteum side is expected and may contribute to healing.

the blood, and are then readily delivered to tissues even with poor blood supply. This therapy has neo-vascularization properties and stimulates the immune system. In addition, it may provide a direct kill of certain bacteria.

Infantile osteomyelitis

Infantile osteomyelitis usually occurs a few weeks after birth, and commonly involves the maxilla. Although the exact etiology remains unclear, infantile osteomyelitis is thought to involve perinatal trauma, infection of the maxillary sinus, contaminated nipples or hematogenous seeding of bacteria from other body sites.

This disease could spread to involve the eye and brain. Therefore there are potential risks of serious optic and cerebral sequelae, facial deformities, serious damage to jaw growth, and loss of teeth and bone. Despite a historically high mortality rate, largely due to spread to the brain and sepsis, death is today rare, and morbidity has been greatly diminished with the advent of antibiotics.

The local signs of this infection are swelling of the face with edema of the eyelids and subperiosteal abscesses on the alveolar mucosa and palate. Common systemic signs include high fever, rapid pulse rate, vomiting, delirium, and prostration.

As with acute suppurative osteomyelitis in adults, radiographs are usually of little value in making an early diagnosis. Treatment must be prompt and aggressive to prevent permanent optic damage, neurologic complications, and loss of teeth buds and bony tissues. Management commonly consists of the use of intravenous antibiotics and drainage of the abscess. Although *S. aureus* is the most common pathogen involved, involvement of other bacteria also occurs. Therefore the choice of antibiotic should again be based on microbiologic examination of spec-

imens, although penicillin and clindamycin are recommended for empiric use. Due to the risk of surgical damage to tooth buds, a conservative approach in sequestrectomy should be considered.

Chronic diffuse sclerosing osteomyelitis

Chronic diffuse sclerosing osteomyelitis is a non-suppurative form of osteomyelitis. It is usually found in the mandible and is characterized by recurrent pain and swelling, no suppuration or abscess formation, radiographic appearance of variable amounts of bone deposition and diffuse sclerosis with ill defined borders in the jaw, and insidious onset and persistence of disease.

The etiology and pathogenesis of the disease remain unclear. Possible etiologies include hyperactive immunological responses, chronic tendoperiostitis from muscle overuse, and a manifestation of synovitis, acne, pustulosis, hyperostosis or osteitis (SAPHO) syndrome.^{105–107}

A history of intermittent pain, swelling, trismus, pressure, and paresthesia are important clinical findings for diagnosis. Radiographic investigation demonstrates intermingled sclerotic and osteolytic lesions with a solid periosteal reaction and/or external bone resorption. In cases with a long-standing disease history, osteosclerosis becomes increasingly marked (Fig. 29.56).

There is generally no specific laboratory test for diagnosis. As with suppurative osteomyelitis, panoramic radiograph, radionuclide scanning, CT scans, and MRI techniques are useful for diagnosis and follow-up investigations.

Diffuse sclerosing osteomyelitis is difficult to eradicate and may persist for years. Treatment is usually aimed at addressing the symptoms rather than being curative, and includes NSAIDs, corticosteroid,

Fig. 29.56 Two cases of chronic diffuse sclerosing osteomyelitis. Panoramic radiographs shows osteosclerosis around mandibular premolar (a) and molar (b). MRI of the latter patient shows bony inflammation in the mandible (c). Photographs courtesy of Professor E. Yamamoto (Kanazawa University) and Professor H. Sakamoto (Tokai University).

HBO therapy, and muscle relaxants. Antimicrobial treatment is usually unsuccessful, and surgery, including debridement and decortication, is often of limited success.

Garré's sclerosing osteomyelitis

Garré's sclerosing osteomyelitis is another form of non-suppurative osteomyelitis. Its name originates from a Swiss surgeon, Dr Carl Garré, who first reported the clinical complications of acute osteomyelitis in 1893.¹⁰⁸ This disease is characterized by an active periosteum proliferation, and formation of subperiosteal bone with no purulent exudate or abscess formation (Fig. 29.57). Garré's sclerosing osteomyelitis is believed to result from an over-inflammatory reaction in the periosteum. It occurs commonly in children and young adults as these ages are the peak periods for periosteal osteoblastic activity. It usually affects the lateral surface of the body of the mandible. Periapical abscesses and post-extractive infections are common etiologies, although there are some cases with an undetectable origin of the disease.

Common clinical features include a localized, unilateral and hard mandibular swelling with little tenderness. The swelling may result in facial asymmetry, although the overlying skin commonly appears normal. Pain can be episodic with dormant periods. There is no apparent systemic sign such as fever, leukocytosis or lymphadenopathy. Radiological findings show a thickened cortical bone and "onion skin" appearance due to periosteal new bone formation.

Differential diagnosis includes Ewing's sarcoma, osteosarcoma, fibrous dysplasia, cherubism, syphilitic osteomyelitis, and healing fracture callus. Treatment involves elimination of the cause of infection, commonly done by tooth extraction or endodontic treatment; antibiotic therapy is usually unnecessary. Surgical remodeling can be considered in cases where there is no spontaneous regression.

Osteoradionecrosis

Osteoradionecrosis is bone necrosis in previously irradiated tissues and in the absence of tumor persistence or recurrence (Fig. 29.58). It is the most significant complication of radiation therapy for malignant

Fig. 29.58 Panoramic radiograph of a 60-year-old man with osteoradionecrosis of the left mandible. The disease became apparent 14 months after radiotherapy (62 Gy) for cancer of the floor of the mouth.

tumors of the head and neck, resulting from both the short- and long-term effects of radiation therapy on bone and the surrounding soft tissue. The incidence of osteoradionecrosis is between 5% and 15%,¹⁰⁹ and most cases occur in the mandible. The condition is irreversible and will not heal spontaneously. In the majority of cases, the disease is induced by secondary trauma, but it does occur spontaneously in 10–35% of cases.^{109,110} The most prominent etiological factor is the reduction in the vascularization potential of tissues.^{109–111} The resulting hypovascular and hypoxic conditions jeopardize cellular activity, collagen formation, and wound healing capacity. Risk factors for the condition include higher radiation doses, tooth extraction after radiotherapy, and poor oral hygiene.¹¹²

A variety of clinical presentations can be seen ranging from small asymptomatic regions of exposed bone that remain stable over time through to full-blown osteonecrosis characterized by severe pain, orofacial fistulas, a foul-smelling necrotic jaw bone with suppuration and pathological fracture.

Diagnosis is primarily based on the patient's medical history and clinical signs and symptoms such as severe pain, non-healing exposed bone within the treatment area after completion of radiotherapy, and incidents of recurrent infections. Plain radiographs may show decreased bone density and occasionally fractures.

Management of osteoradionecrosis remains extremely difficult and time-consuming. Early stages of the disease can be managed with less aggressive treatments such as frequent irrigation with saline,

Fig. 29.57 Garré's sclerosing osteomyelitis in the mandibular angle of a young woman. Possible cause is pericoronitis in the mandibular third molar. (a) Facial asymmetry and unilateral and hard mandibular swelling with no inflammatory change in overlying skin are evident. (b) A panoramic radiograph shows thickened cortical bone and a bony lesion around the mandibular angle.

analgesics, antibiotics, local debridement, and sequestrectomy. However, patients who present with extensive lesions or in whom less invasive therapy has failed, often require aggressive resection, necessitating some form of reconstruction. Pathogenic fracture is unlikely to heal and therefore excision of the necrotic ends of both fragments and eventual replacement with a bone graft is required. HBO therapy is often used in conjunction with surgery.

Bisphosphonate-related osteonecrosis of the jaw (BRONJ)

Bisphosphonates are a class of drugs that inhibit osteoclast action and the resorption of bone. These agents are generally used in the prevention and treatment of osteoporosis, osteitis deformans, bone metastasis of malignant tumors with or without hypercalcemia, multiple myeloma and other conditions that feature bone fragility. Intravenous and oral preparations are available and the former is primarily used in the management of bone metastasis and the latter often prescribed to treat osteoporosis and osteopenia.

In 2003, the first case of a BRONJ patient, who exhibited non-healing, exposed necrotic bone in the jaw during bisphosphonates therapy, was published.¹¹³ Since then, similar cases have been reported from many countries. It has now been recognized that use of bisphosphonates can cause osteonecrosis of jaw (BRONJ) (Fig. 29.59). It is hypothesized that the pathogenesis of BRONJ might be primarily related to the drug-mediated inhibition of osteoclast function and bone remodeling.^{114,115}

Definition and epidemiology of BRONJ

Despite no diagnostic criteria having been globally accepted, the American Association of Oral and Maxillofacial Surgeons (AAOMS) proposed that involvement of BRONJ can be considered if all of the following three characteristics are present: (1) current

or previous treatment with a bisphosphonate; (2) exposed, necrotic bone in the maxillofacial region that has persisted for more than 8 weeks; and (3) no history of radiation therapy to the jaws.¹¹⁶

BRONJ is usually found in the mandible and the large majority of cases are related to high-dose intravenous administration. The actual incidence remains unclear because of a lack of published studies of sufficient sample size. Estimates of the cumulative incidence of BRONJ in patients treated with intravenous bisphosphonates range from 0.8–12%.¹¹⁶ The incidence of BRONJ associated with oral bisphosphonates is reported to be from 0.01–0.04%.¹¹⁷ With an increased recognition of the condition, an enhanced duration of drug exposure, and longer follow-up period, it is likely that the incidence will rise. The suggested predisposing factors for the development of BRONJ are extensive. These include intravenous bisphosphonate administration, an increased duration of drug exposure, involvement of the mandible, the presence of thin mucosa overlying bony prominences as seen with tori and bony exostoses, the occurrence of dentoalveolar surgery including tooth extraction, implant surgery, periodontal surgery, a history of inflammatory dental disease, old age, patients of Caucasian race, involvement of a tumor (multiple myeloma > breast cancer > other cancers), corticosteroid therapy, diabetes, smoking, alcohol use, poor oral hygiene, and use of chemotherapeutic drugs.^{116,118}

Prevention of BRONJ

Despite the fact that osteonecrosis can occur spontaneously in patients receiving bisphosphonates, the majority of affected patients experience this complication after dentoalveolar surgery. Therefore, patient education in maintaining good oral hygiene and dental care is of importance in preventing dental disease that may require dentoalveolar surgery.

Prior to treatment with an intravenous bisphosphonate, patients should have a thorough oral examination, any unsalvageable teeth should be removed,

Fig. 29.59 Intraoral view of two patients with bisphosphonate-associated osteonecrosis. (a) An exposed and partly necrotic bone of mandible in the lingual aspect is evident (case 1). (b) Extensive exposure of necrotic bone (case 2).

all invasive dental procedures should be completed, and optimal periodontal health should be achieved. If systemic conditions permit, initiation of bisphosphonate therapy should be delayed until dental health is optimized. Once intravenous bisphosphonate therapy starts, procedures that involve direct osseous injury should be avoided.

In the case of oral bisphosphonates, elective dento-alveolar surgery is generally not contraindicated. The risk of developing BRONJ appears to increase when the duration of therapy exceeds 3 years, although this timeframe may be shortened in the presence of certain comorbidities, such as chronic corticosteroid use.¹¹⁶ For individuals who have taken an oral bisphosphonate for less than 3 years and have no clinical risk factors, no alteration or delay in the planned surgery is necessary. These patients should, however, be adequately informed of the risks of compromised bone healing. For those patients who have taken an oral bisphosphonate for less than 3 years and have also taken corticosteroids concomitantly, the prescriber should be contacted to consider discontinuation of the oral bisphosphonate (drug holiday) for at least 3 months prior to and 3 months after oral surgery, if systemic conditions permit, because it may lower the risk of BRONJ. A break from drug therapy should also be considered in patients who have taken an oral bisphosphonate for more than 3 years with or without any concomitant prednisone or other steroid medication.

The management principles of BRONJ

An effective treatment for BRONJ has not yet been established. In this section, management of BRONJ is discussed based on the guidance proposed by the AAOMS in 2007.¹¹⁶

Patients with established BRONJ generally exhibit a poor response to the established surgical treatment algorithms for osteomyelitis. Therefore, conservative debridement of necrotic bone, pain control, infection management, use of antimicrobial oral rinses, and withdrawal of bisphosphonates are preferable to aggressive surgical measures. Surgical debridement has been variably effective in eradicating necrotic bone, but overinvasive procedures might aggravate bony necrosis or expand the area of lesion. Clinicians should be aware that it is difficult to obtain a surgical margin with viable bleeding bone as the entire jawbone has been exposed to the pharmacologic influence of the bisphosphonate. Areas of necrotic bone that are a constant source of soft tissue irritation should be removed or recontoured without exposure of additional bone. Loose segments of bony sequestrum should be removed without exposing uninvolved bone. The extraction of symptomatic teeth within exposed, necrotic bone should be considered because it is unlikely that the extraction will exacerbate the established necrotic process. Symptomatic patients with pathologic mandibular fractures may

require segmental resection and reconstruction with a reconstruction plate. The potential for failure of the reconstruction plate because of the generalized effects of the bisphosphonate exposure needs to be recognized by the clinician and patient.

Discontinuation of intravenous bisphosphonate therapy shows no short-term benefit. However if systemic conditions permit, long-term discontinuation may be beneficial in stabilizing established sites of BRONJ, reducing the risk of new site development and relieving clinical symptoms. Discontinuation of oral bisphosphonate therapy in patients with BRONJ has been associated with gradual improvement in clinical disease. Discontinuation of oral bisphosphonates for 6–12 months might result in either spontaneous sequestration or resolution after debridement surgery. If systemic conditions permit, modification or cessation of oral bisphosphonate therapy should be done in consultation.

Staging categories and treatment strategies of BRONJ

The AAOMS has proposed the use of the staging categories and treatment strategies that are presented in Table 29.28:

- *Patients at risk.* Patients who have no apparent exposed or necrotic bone but have been treated with either intravenous or oral bisphosphonates are considered to be at risk of developing BRONJ. Although the patients of this group do not require any treatment, these patients should be informed of the risks of developing BRONJ.
- *Stage 1 patients.* Patients who show exposed, necrotic bone but are asymptomatic and have no evidence of infection. These patients benefit from the use of oral antimicrobial rinses, such as 0.12% chlorhexidine. No surgical treatment is indicated.
- *Stage 2 patients.* Patients who exhibit exposed, necrotic bone with pain and clinical evidence of infection. Pain should be controlled through the systemic use of analgesics. The use of oral antimicrobial rinses in combination with systemic antibiotic therapy is recommended. Preferred antibiotics include the members of penicillin group, quinolones, metronidazole, clindamycin, doxycycline, and erythromycin, although if microbiologic data is available, the antibiotic regimen should be adjusted accordingly. In some refractory cases, patients may require combination antibiotic therapy, long-term antibiotic maintenance, or a course of intravenous antibiotic therapy. Only superficial debridement to relieve soft tissue irritation is advocated.
- *Stage 3 patients.* Patients show exposed, necrotic bone with pain, infection, and one or more of the following: pathologic fracture, extraoral fistula, or osteolysis extending to the inferior border. Pain control is important for preservation of quality of

Table 29.28 Staging and treatment strategies for bisphosphonate-associated osteonecrosis.

Patient at risk	No apparent exposed/necrotic bone in patients who have been treated with either oral or IV bisphosphonates	No treatment indicated Patient education
Stage 1	Exposed/necrotic bone in patients who are asymptomatic and have no evidence of infection	Antibacterial mouthrinse Clinical follow-up on a quarterly basis Patient education and review of indications for continued bisphosphonate therapy
Stage 2	Exposed/necrotic bone associated with infection as evidenced by pain and erythema in the region of the exposed bone with or without purulent drainage	Symptomatic treatment with broad-spectrum oral antibiotics, e.g. penicillin, cephalexin, clindamycin, or first-generation fluoroquinolone Oral antibacterial mouthrinse Pain control Only superficial debridement to relieve soft tissue irritation
Stage 3	Exposed/necrotic bone in patients with pain, infection, and one or more of the following: pathologic fracture, extraoral fistula, or osteolysis extending to the inferior border	Antibacterial mouthrinse Antibiotic therapy and pain control Surgical debridement/resection for longer-term palliation of infection and pain

life. Surgical debridement/resection in combination with antibiotic therapy might offer long-term palliation with resolution of acute infection and pain, but deliberation is necessary to determine if an aggressive procedure is actually required.

Dental fistulae

A fistula is an abnormal passage or communication between two internal organs or leading from an internal organ to the surface of the body. Various pathologic conditions are involved in the creation of a fistula. In the oral and maxillofacial region, odontogenic infections such as periapical abscesses, severe periodontitis, and pericoronitis are common causes of fistulae. Additional etiologies include peri-implantitis, osteomyelitis and osteoradionecrosis of the jaw, actinomycosis, postextraction infection, traumatic infection, and surgical wound infection (surgical site infection). A fistula can also involve non-infective entities such as salivary gland diseases, oral malignant tumor, and oroantral communication caused iatrogenically.

This section discusses the clinical features and management of those fistulae related to odontogenic infections (dental fistulae). Dental fistulae are often referred to as dental sinus tracts.¹¹⁹ Dental fistulae formed within the mouth are internal dental fistulae, and those created on the skin surface of the face are termed cutaneous dental fistulae or extraoral dental fistulae (cutaneous dental sinus tracts) (Fig. 29.60). In terms of pathological characteristics, a fistula consists of granulation and/or epithelial tissues.¹²⁰

Pathogenesis and clinical findings

The purulent by-products produced by odontogenic infection are initially collected within alveolar bone. The purulent by-products of pulpal infection will

**Fig. 29.60** Intraoral dental fistula and extraoral dental fistula.

seek the path of least resistance and move through bone and soft tissue. Once the cortical plate has been penetrated, the fistula's exit point is determined by the location of muscle attachments and fascial sheaths.

The series of paths (fistular tracts) commonly end within the connective tissue. However, occasionally they reach the surface of the oral mucosa or skin and establish the fistula. A fistula is usually created spontaneously but occasionally forms as a result of incision and drainage of an abscess. A small amount of pus and other purulent material can constantly drain through the fistular tract with the result that pus does not accumulate within the bone. This drainage releases the pressure inside the alveolar bone and prevents a transformation into an acute infection. Such drainage does, however, impede the healing of the fistula; as a result, once established, it may not close

spontaneously unless the focus is treated adequately or eliminated.

Intraoral dental fistulae

An intraoral dental fistula starts with an abscess in the alveolar bone and ends on the gingiva or on the surface of the palatal mucosa. A single fistula is common but one focus can produce multiple fistulae.

An intraoral dental fistula is usually seen as a small and well limited oval or round swelling with erythema, or as a polyp-like lesion (Fig. 29.61). Therefore, less experienced clinicians may sometimes regard the lesion as a neoplasm. This presentation results from inflammation and formation of granulation. If granulation is minimal, the fistula may develop as a 'crater-like' lesion without swelling. The fistula itself does not produce pain or tenderness.

Extraoral dental fistulae

An extraoral dental fistula is an abnormal passage or communication between lesions of chronic odontogenic infection within the alveolar bone and the cutaneous surface. An extraoral dental fistula commonly forms in the vicinity of the focus. In the majority of cases, the focus is a chronic infection of mandibular teeth and thus the fistula frequently appears on the chin, cheek, submental or submandibular region.

Fig. 29.61 Intraoral dental fistulae associated with periapical abscess (a) and pericoronitis (impacted tooth) (b).

Fig. 29.62 Extraoral dental fistula.

However, an extraoral dental fistula occasionally forms at a location away from the focus.

An extraoral dental fistula appears as a soft, slightly depressed nodule or papule on the skin, often fixed to underlying structures (Fig. 29.62). The lesion often has a central opening for discharge of fluid materials from the focus. Palpation of the surrounding tissue may produce pus or purulent materials, which could support the diagnosis.

Diagnosis

As intraoral and extraoral fistulae have similar clinical appearances to other types of lesions that can occur in the oral and maxillofacial region, they may be misdiagnosed, leading to inappropriate antibiotic therapy, aspiration or surgery.

Intraoral and dental examinations using radiographical analysis are necessary for fistula diagnosis (Fig. 29.63). The presence or absence of a periapical abscess, necrotic pulp tissue, periodontal disease, pericoronitis, crack or fracture of tooth, and foreign body in an extraction socket should carefully be determined. The fistular tract can be traced by gentle probing using an instrument with a blunt tip or by obtaining a periapical radiograph following insertion of a gutta-percha cone into the fistular tract (Fig. 29.64).

An extraoral dental fistula should be distinguished from a granuloma, benign and malignant tumor, actinomycosis, and furuncle. Tumor, mucocoele, and epulis need also to be differentiated from intraoral fistulae.

Treatment

Treatment of the focus is a necessity in the management of fistulae. Treatments include tooth extraction, endodontic therapy, apicectomy, professional periodontal treatment, and debridement of extraction socket. If the causative tooth is salvaged, then the risk of recurrence will generally increase. The persistence of a foreign body, infected granulation, dying bone or sequester in the socket after tooth extraction are also causes of recurrence.

Antibiotic therapy alone is not effective in completely resolving the fistula without recurrence. Similarly, surgical removal of the fistula without resolution of the focus also yields limited success.

Fig. 29.63 (a) Extraoral dental fistula involved in a periapical abscess in the vicinity of the mandibular first molar. (b, c) Careful oral inspection and radiographic examination illustrates the fistula and involved tooth.

Fig. 29.64 (a) Insertion of a gutta-percha cone into the fistular tract for tracing. (b) A radiograph indicates the involvement of an abscess at the root furcation of the mandibular molar.

In the case of an intraoral fistula, once the focus is treated adequately, the fistula will heal spontaneously without any additional treatment. However, in the case of an extraoral dental fistula, a combination of focus treatment and surgery for the fistula (Fig. 29.65) may be required because the fistula tract may harbor small foreign bodies or large amounts of infected granulations and epithelial tissue that may prevent complete healing and may cause recurrence. In addition, spontaneous closure of the fistula often causes a residual umbilication of the skin that may be esthetically unappealing (Fig. 29.66). If an esthetically unac-

ceptable scar persists after healing of the fistula, additional plastic surgery may be required.

Acute necrotizing ulcerative gingivitis

Acute necrotizing ulcerative gingivitis (ANUG) is unique in clinical presentation and course. Its clinical presentation is distinctive from all other periodontal diseases. ANUG is characterized by a rapidly progressive ulceration typically starting at the tips of the

Fig. 29.65 The procedure for surgical removal of an extraoral dental fistula (a). After cutaneous incision (b), the skin around the margin of the fistula is undermined (c). It will be helpful to make an esthetic wound closure. A funnel-shaped piece is removed down to the alveolar bone (d). The removed piece contains a cord-like structure extending from the external opening to the alveolar process. A piece of gauze is inserted into the fistular tract from the intraoral side and passed to the extraoral side through the fistula tract. The residual pus, granulation, and necrotic tissue around the fistular tract are scrubbed out by moving the gauze back and forth (e). Approximation of all tissue layers to avoid formation of a postoperative dead space. Cutaneous surface is sutured esthetically (f). Illustrations were redrawn with permission from Ohtani T, *et al.*, editors, *Atlas of Oral and Maxillofacial Surgery*, vol 2. Tokyo: Ishiyaku Publishers, 1988.¹²¹

Fig. 29.66 Residual cutaneous umbilication associated with closure of an extraoral dental fistula.

interdental papilla, spreading along the gingival margins, and going on to acute destruction of the periodontal tissue with severe pain, interdental necrosis, and bleeding (Fig. 29.67).

Etiology and pathogenesis

The etiology of ANUG is not fully understood. However, spirochetes and *Fusobacterium* species are thought to be associated with the etiology. Recent reports suggest that other oral strict anaerobes, including *Prevotella* species, are also involved in the disease.¹²² Pre-existing gingivitis, nutritional deficiency, tobacco smoking, psychological stress, and immunosuppression have been implicated as predisposing factors.¹²³

Clinical features

The clinical presentation of ANUG comprises of a punched out ulcer, which is involved primarily with

Fig. 29.67 Acute necrotizing ulcerative gingivitis. Ulceration at the tips of the interdental papilla and destruction of the periodontal tissue are evident. In extreme cases, denudation of dental root occurs (right).

the tips of interdental papillae and the labial or lingual margin or both. Involvement may be a single tooth, a group of teeth or throughout the mouth, but the condition is rare in edentulous patients. The mandibular anterior region is most frequently affected.

The edge of the ulcer is usually defined by erythema and edema and often the lesion itself is covered by a grey pseudomembranous slough. The affected area often becomes highly sensitive to touch, and produces a constant radiating, gnawing pain, which is intensified by hot food or mastication. Spontaneous gingival bleeding upon exposure to the slightest stimuli can occur. In addition ANUG is often accompanied by marked halitosis and foul taste.

Mild to moderate cases may manifest as local lymphadenopathy with a slight elevation in body temperature. However, in its most severe form, high fever, increased pulse rate, leukocytosis, headache, loss of appetite, lassitude, and insomnia can all result.

ANUG may subside spontaneously, although the disease has the potential to cause progressive destruction of periodontium and denudation of dental root with systemic complications.

Diagnosis

The patient's clinical history and symptoms are often sufficient information to permit diagnosis. If there is uncertainty, ANUG can be confirmed rapidly by microscopic examination of a Gram-stained smear taken from an area of ulceration and should reveal numerous fusobacteria, medium-sized spirochetes and acute inflammatory cells.

Management

Initial management should involve a thorough mechanical cleaning and debridement of the teeth in the affected area. The use of hydrogen peroxide mouthwashes, both to provide mechanical cleaning and also to serve as an oxidizing agent, has been recommended, although the benefit of such treatment is not universally accepted. The importance of local

measures cannot be overemphasized, but symptoms will improve more rapidly if the patient is also given a systemic antimicrobial agent. Metronidazole (200mg 8-hourly or after meals) prescribed for 3 days will usually produce a dramatic improvement within 48 hours. In the long term, good oral hygiene therapy prevents further gingival damage.

Peri-implantitis

Dental implant treatment aims to restore oral function that has been disrupted through the loss of teeth. The surgical placement of an implant has become a widely accepted approach to replace missing teeth. Despite various types of implant being available, the large majority of them are designed to osseointegrate within the bone. Osseointegration is defined as the direct structural and functional connection that occurs between living bone and the surface of implant. Despite most implants exhibiting long-term success, complications may occur in a small percentage of cases. Any pathologic changes that occur in the peri-implant tissue are generally categorized as a form of peri-implant disease. Inflammatory changes confined to the soft tissue surrounding an implant are diagnosed as peri-implant mucositis (Fig. 29.68). Progressive peri-implant bone loss in conjunction with a soft tissue inflammatory lesion is termed peri-implantitis. Despite a limited incidence of peri-implantitis, the condition is frequently encountered by dentists and this simply reflects the high number of people who currently receive implant treatment. As with odontogenic infections, peri-implantitis has the potential to cause extensive maxillofacial cellulitis, osteomyelitis, and maxillary sinusitis.

Etiology and pathogenesis

Although the exact etiology of peri-implantitis remains unclear, the infection is thought to occur due to the presence of oral anaerobic bacteria in plaque biofilm adhering to the implant. Of course, host susceptibility to infection is a significant factor in

Fig. 29.68 Peri-implant diseases are divided into peri-implant mucositis and peri-implantitis. Peri-implantitis involves bone loss, whilst the bone is not significantly affected in the case of peri-implant mucositis. Peri-implant mucositis and peri-implantitis are analogous to gingivitis and periodontitis in natural teeth, respectively.

addition to the bacterial contamination. Unlike in natural teeth, there is no periodontal ligament between the implant and supporting bone. In addition, the arrangement of collagen fibers around implants is different from that of natural teeth. It is these differences in the nature of attachment of soft tissue to both the implant and natural tooth, which result in peri-implant tissues being more sensitive to bacterial infection and tissue breakdown.

Poor oral hygiene, smoking and a previous history of periodontitis predispose patients to peri-implantitis.¹²⁴ An immunocompromising condition, impaired bony metabolism, and inadequate implant surface are also suggested to be risk factors.

Microbiology

Implantitis with advanced pocket formation yields high levels of spirochetes and Gram-negative bacilli (*Fusobacterium* species, *Prevotella* species, *Porphyromonas* species, *Tannerella forsythensis*, and *Aggregatibacter actinomycetemcomitans*), whereas successful implants are characterized by very low numbers of cultivable organisms with a predominance of Gram-positive cocci.¹²⁵ These microbial shifts are very similar to those that occur around natural teeth.

Clinical features

Peri-implant mucositis is analogous to gingivitis and is primarily a disorder caused by plaque accumulation. It may be identified clinically by bleeding on probing, and redness and swelling of the soft tissue.

Peri-implantitis usually produces little subjective symptoms in its initial phase. As it progresses, gingival bleeding and tenderness, pain at chewing, purulent exudates from the pocket, malodor, bad

Fig. 29.69 (a) Intraoral photograph of a patient with severe peri-implantitis. Pus discharge from the pocket with erythema is evident. (b) A radiograph shows significant bone loss around the implants.

Fig. 29.70 A radiograph of a patient with various degrees of peri-implantitis.

taste, and gingival recession with gingival swelling and erythema will appear (Fig. 29.69). Bone levels decrease with the loss of integration (Fig. 29.70). Bone destruction may proceed without any notable signs of implant mobility until osseointegration is completely lost, because the bottom part of the implant may still retain a degree of osseointegration.

Diagnosis

The clinical diagnosis of implantitis is generally based on inspection of the implant and peri-implant tissues, the patient's subjective symptoms, probing of the pockets, and radiographic examination.

The bone supporting the implants might be absorbed from the alveolar crest side as a normal postoperative alteration (vertical bone loss, <0.2 mm, annually after first year of function)¹²⁶ and this should be taken into account in the radiographic study. Probing of the pockets is useful to measure pocket depth and to determine the presence or absence of bleeding on probing and suppuration. Due to the previously mentioned differences in attachment between implants and natural teeth, actual pocket depths are not used as determinative indices of the disease as they are for periodontitis. A significant increase in the pocket depth and bone loss in the follow-up period suggests peri-implantitis and its progression.

Treatment

Treatment for salvaging the implant consists of the patient's own self-care with respect to their oral hygiene and also professional treatment. The implant surface is usually contaminated with soft tissue cells, bacteria, and bacterial by-products. These contaminants will compromise therapeutic effects and induce further breakdown of the peri-implant tissue. Subgingival debridement, removal of calculus and cleaning, and decontaminating the implant surface are therefore necessary.

Mechanical cleansing and local irrigation can be effective in the treatment of peri-implant mucositis. Furthermore, the adjunctive use of antimicrobial mouthrinses may enhance the outcome of mechanical therapy of mucositis lesions.

Treatment of peri-implantitis is generally difficult, and there are no treatment principles that have been universally accepted. Non-surgical therapy alone may not be effective. It has been reported that guided bone regeneration (GBR) and bone graft techniques result in various degrees of success.¹²⁴ However, such techniques do not address disease resolution but rather merely attempt to fill the osseous defect. Implant removal should be considered in cases where osseointegration has been reduced severely and bone loss has extended into the apical half of the implant, when the implant demonstrates mobility, or if peri-implantitis causes significant suppuration. After the implants are removed, the ridge defects usually reconstruct spontaneously.

If peri-implantitis causes extensive infection, such as maxillofacial cellulitis, osteomyelitis, and maxillofacial sinusitis, appropriate treatment is required. Due to the similarity in microbiology and pathogenesis, the principles of treatment of implant diseases are the same as for diseases of odontogenic origin.

Infection of the maxillary sinus

Maxillary sinusitis is an inflammation of the maxillary sinuses. As described in the Biomedical sciences

section of this chapter, the maxillary sinuses are primarily lined by mucoperiosteum. The antral mucus glands produce mucus and this normally drains to the nose through the sinus opening or ostium. The secretion and drainage of mucus are parts of the local host defense system and play an important role in maintaining microbial homeostasis in the sinus. If infection or an allergic reaction affects the sinus, the antral mucosa may become thickened with pathogenic associated changes, including edema, degeneration, hyperplasia or hypertrophy. Mucosal thickening may induce obstruction of the ostium with an associated reduction in mucus drainage and subsequent overgrowth of pathogenic bacteria. If left untreated or inadequately treated, infection of the maxillary sinus may spread to involve other subgroups of the paranasal sinus.

Maxillary sinusitis can be divided into acute and chronic, based on duration of disease, and odontogenic or non-odontogenic based on the etiology. Non-odontogenic factors, especially upper respiratory tract infections and allergic reactions, are the most common etiologies, with approximately 10% of all maxillary sinusitis cases being of dental origin.¹²⁷

Maxillary sinusitis of odontogenic origin

Unlike non-odontogenic sinusitis, odontogenic maxillary sinusitis usually manifests unilaterally and its pathophysiology, microbiology, and management are different from those of non-odontogenic sinusitis.

Etiology and pathogenesis

Acute odontogenic maxillary sinusitis primarily results from multiplication of bacteria invading from the mouth or the focus of a dental infection. The distance between the dental root apices and the antral floor generally correlates with the likelihood of sinusitis. Since the maxillary premolar and molar teeth have the closest proximity to the antral floor, infection of these teeth, as seen with periapical abscesses, severe periodontitis, peri-implantitis, and postextraction infection, is the most common cause of the disease (Fig. 29.71). Additional etiologies include

Fig. 29.71 Multiplication of bacteria invading from the focus of a dental infection results in odontogenic maxillary sinusitis.

dental or alveolar trauma, odontogenic cysts, maxillary osteomyelitis, iatrogenic or accidental displacement of foreign bodies (e.g. teeth, root tips, dental implants, osseous fragments, bone graft materials, endodontic therapy materials, and fragments of broken instruments) during routine dental treatment or dentoalveolar surgical procedures (e.g. dental extraction and dental implant surgery), and other surgical complications that result in sinus exposure.

Chronic odontogenic sinusitis results from a prolonged low-grade inflammation in the antral mucosa following acute phase or recurrence of acute sinusitis. Some cases induce a primary chronic form that manifests without an acute episode. In chronic sinusitis, the antral mucosa is thickened with edema, infiltration of leukocytes and fibers, sometimes accompanied by the creation of polyps.

Microbiology

Maxillary sinusitis usually involves mixed microflora. Acute sinusitis of non-odontogenic origin predominantly yields aerobic bacteria, in particular *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Staphylococcus aureus*, which are detectable in disease-free nasal cavities.^{128,129} In contrast, the microbiology of acute odontogenic sinusitis is somewhat similar to that of a dentoalveolar abscess. The most frequent bacteria isolated include viridans streptococci and anaerobes such as *Peptostreptococcus*, *Porphyromonas*, *Prevotella*, and *Fusobacterium*.¹³⁰ Nevertheless, bacteria residing in the nasal cavity and nasopharynx may be present in the microflora of odontogenic sinusitis.¹³⁰ Therefore the microbiology of this disease is complex with a wide variety of organisms involved.

The microflora of chronic sinusitis is polymicrobial, with viridans streptococci and anaerobes, and is similar to the organisms isolated from acute odontogenic sinusitis.¹³⁰ However, clinical specimens from chronic sinusitis often yield reduced numbers of bacteria.

Clinical signs and symptoms

Acute odontogenic maxillary sinusitis

As with other acute infections, acute maxillary sinusitis results in pain and systemic upset. Common signs and symptoms include dull or intense pressure-like pain, erythema, swelling of the cheek and the anterior maxilla, pressure or fullness in the vicinity of the maxillary sinus, headache, malaise, fever, oral malodor, mucopurulent rhinorrhea, nasal congestion or obstruction, and drainage of foul-smelling mucopurulent materials into the nasal cavity and nasopharynx (postnasal drip). Edema of the eyebrow occasionally accompanies the infection. In cases originating from periapical abscesses, the disease often starts with toothache and swelling in the gingiva and the buccal vestibule. A blood examination demon-

Fig. 29.72 Discharge of pus from the antral cavity through the extraction socket.

strates increased leukocyte count and an elevated CRP level.

Acute maxillary sinusitis has the potential to cause serious complications. Of particular significance are orbital cellulitis, cavernous sinus thrombosis, meningitis, and intracranial abscesses, as these can lead to a loss of vision, severe neurologic deficits, or even death.

Chronic odontogenic maxillary sinusitis

Unlike acute forms of the infection, little or no systemic upset occurs with chronic odontogenic maxillary sinusitis, although transformation into the acute form can occur spontaneously. Local signs and symptoms are generally subtle but malodor, persistent pus discharge from the oroantral fistula (Fig. 29.72), nasal congestion, and discharge, with or without a postnasal drip, are not uncommon. Toothache during chewing, increased mobility of teeth, migraine, dull headache, and anterior maxillary tenderness are also possible symptoms. Some patients have little discomfort, probably due to incomplete osteomeatal obstruction. Such "symptom-free" sinusitis may be detected by chance when performing radiographic analysis during routine dental practice or when encountering "abnormal" pus discharge from a root canal or extraction socket during dental treatment. There is generally no specific blood test for diagnosis and indeed little change in blood test parameters are associated with this infection.

Diagnosis

Imaging

Radiologic imaging is an important tool in establishing correct diagnosis. Conventional Water's, frontal, and lateral radiographs have been used in establishing a diagnosis. Due to thickened antral mucosa and fluid accumulation, a range of opacification in the affected sinus is often evident. Since the disease is usually unilateral, comparison in opacification between opposite sides is often helpful. Radiographic translucency level is generally lower in the affected

sinus than in the unaffected site (Fig. 29.73). Periapical and panoramic radiographs are useful in determining the probable source and assessing the relation and proximity between the root apices and the antral floor. A CT scan is often considered the gold standard imaging method for the maxillary sinus in developed countries and it provides much more reliable information compared with traditional radiographs.

Diagnosis principles

Diagnosis of the maxillary sinusitis of odontogenic origin is generally based on a careful dental and medical examination that includes evaluation of the patient's signs and symptoms, past medical history, adequate imaging studies, and laboratory examination. In addition, otolaryngological evaluation using rhinoscopy, nasal and sinus endoscopy, and aspiration of sinus contents for cytologic and microbiologic assessments can assist in making the correct diagnosis.

Differentiation from carcinoma, aspergillosis, and cystic disease in the maxillary sinus or maxillary bone is required because of their similar features in imaging studies.

Fig. 29.73 (a) The Water's radiograph reveals opacification of the affected sinus, in which the radiographic translucent level is lower compared with the unaffected site. (b) CT scan demonstrates thickened sinus mucosa and fluid accumulation within the affected sinus. (c) Periapical abscess of the maxillary first molar is the probable cause as shown on the panoramic radiograph.

Treatment principles

Both elimination of the infection source and treatment of the antral lesion are necessary for the complete resolution and prevention of recurrence. Once treatment starts, the patient should be carefully evaluated until the condition has completely resolved.

Acute maxillary sinusitis

In the case of acute maxillary sinusitis, antimicrobial therapy is an essential part of treatment. Early and aggressive antibiotic therapy and elimination of the source may provide a full cure without prolongation of the inflammatory process. Penicillin, clindamycin, and metronidazole are adequate drugs of initial choice. However, because of the range of microorganisms that may be involved, purulent material should be obtained for culture and sensitivity testing whenever possible and the choice of antibiotic should be based on these laboratory results. Individual treatment modalities will generally result in more successful outcomes. An increase in drug dose and intravenous administration of antibiotic are especially recommended in moderate to severe cases.

Relief of pain and reduction of the nasal mucosal edema are important and can be achieved through the use of analgesics and antihistamines, respectively.

Drainage serves to reduce pain intensity, prevents disease progression, and encourages resolution. Early tooth extraction and endodontic therapy are recommended because the extraction socket and opened root canal are then available as a route of drainage. Insertion of a piece of gauze containing 0.1% ephedrine (with 4% lidocaine) into the nasal mucosa for 10–15 minutes can relieve mucosal congestion and may result in the promotion of pus drainage through the nasal passage as it expands the sinus ostium. Surgical enlargement of the natural drainage channels using an endoscope is also effective although it may need the involvement of a specialist of sinus endoscopic surgery.

The treatment outcome should be evaluated based on clinical signs and symptoms, laboratory tests, and imaging studies. Since acute maxillary sinusitis can readily spread to involve other paranasal sinus subgroups with the potential to cause serious complications, patients should be evaluated frequently. If occurrence of such complications is suspected, immediate and aggressive care by a specialist is required.

If little or no response to treatment occurs within several days after start of treatment, it is necessary to reassess the treatment strategy and antibiotic selection. Inadequate drainage with accumulation of pus is the most likely cause of a treatment failure. Drainage by tooth extraction or through the root canal should be reconsidered. Adjacent teeth should also be re-evaluated for possible involvement. Surgical drainage through the nasal passage using an endoscope is an option in severe cases. Depressed

host defense mechanisms can be involved in poor response to treatment. Such factors that may delay recovery should be reassessed and corrected. The involvement of antibiotic-resistant bacteria may be a factor affecting therapeutic outcome, highlighting the importance of selecting the antibiotic regimen based on microbiologic analysis of the clinical specimen. If these data are unavailable, an increased drug dose, or administration of antibiotics with β -lactamase stability or broad antimicrobial spectrum, such as imipenem, ampicillin-sulbactam or co-amoxiclav, should be considered. The authors suggest the use of intravenous clindamycin at high doses in cases where penicillin therapy has failed.

After the visual signs of acute infection (e.g., pain, swelling, fever) have subsided and the infection source has been eliminated, the disease commonly takes one of the following courses:

- Sinusitis heals completely without any post-treatment problems. This is often the course of "fresh" sinusitis with no previous episodes of recurrence, in which the sinus mucosa is not seriously damaged. Early diagnosis and adequate treatment for both sinusitis and disease source are necessary in order to obtain such an outcome. For prevention of recurrence, an additional course of oral antibiotic should be administered within a period of 1–2 weeks.
- Sinusitis itself resolves but an oroantral fistula persists. This situation may occur if a patient has oroantral communication or the fistula was created before treatment (usually involved in development of the present sinusitis) or results from tooth extraction during the present treatment of disease. Since long-standing oroantral communication and oroantral fistulae do not heal spontaneously and can be a cause of disease recurrence, surgical closure is required.
- Symptoms associated with low-grade inflammation in the sinus (e.g. persisting pus discharge from oroantral fistula, malodor, nasal congestion and discharge, postnasal drip, dull headache) persist. In such cases, the disease may be regarded as a chronic infection, although it is necessary to determine if these symptoms are actually associated with the sinusitis. Administration of different types of antibiotics for several more weeks may be warranted. However, most cases require surgical intervention to provide a complete cure. If an oroantral fistula is present, it should be closed surgically after sinus infection is eliminated.
- Visual signs and subjective symptoms are minimal but resolution on imaging study is not obtained in the follow-up period (12 weeks after the treatment). It generally takes time to obtain radiographic resolution, but in this case, low-grade inflammation in the sinus may persist. A follow-up for an additional period whilst reserving sinus surgery is advocated, and the patient should be informed of the increased

risk of infection recurrence and possible necessity of surgical intervention to ensure complete eradication of the infection.

Chronic odontogenic maxillary sinusitis

Treatment involves elimination of the infection source, antibiotic therapy and surgery, with the antibiotic regimen being similar to that for the acute form.

Conservative intervention may be attempted initially, without resorting to sinus surgery. Elimination of the dental source by tooth extraction, apicectomy, endodontic therapy, removal of any involved foreign body, and antibiotic therapy might lead to full recovery. If an oroantral fistula is present, frequent irrigation of the sinus cavity via the fistula can prove effective, although surgical closure of the fistula is required after sinusitis is cured. However, if complete resolution is not achieved by these treatments or if the clinician considers that the disease may not heal using conservative approaches then surgery will be required.

Surgery

The goal of sinus surgery is to remove abnormal tissue that exists inside the sinus cavity and may be involved in the disease or cause delayed healing. Surgery also serves to restore normal drainage through the original antral ostium or created sinus opening.

The Caldwell–Luc operation, a radical surgical procedure, has traditionally been employed to treat chronic sinusitis. In this operation, sinus mucosa is stripped from the antral wall, on the basis that the mucosal lesion is irreversible. However, it has been demonstrated that this pathogenic condition is reversible and the antral mucosa can be conserved through correction of the underlying obstruction by minimal surgical procedures including endoscopic sinus surgery (functional endoscopic sinus surgery).¹³¹ Sinusitis of non-odontogenic origin is primarily treated today with endoscopic sinus surgery. In cases of odontogenic sinusitis, the Caldwell–Luc operation is still widely used, but use of endoscopic sinus surgery is increasing.

Caldwell–Luc procedure

The Caldwell–Luc procedure involves the complete removal of the antral lining and creation of a new opening for more dependent drainage into the nose by the transoral approach (Fig. 29.74). This procedure allows the surgeon to inspect the inside of the sinus with the naked eye and any abnormal tissue or foreign bodies in the sinus can then be easily removed. Moreover, removal of a cyst, apicectomy of causative teeth, and surgical closure of the oroantral fistula can be performed concomitantly using the same surgical wound. This procedure is also useful in cases where endoscopic sinus surgery has failed. However, there are several disadvantages, including increased times

Fig. 29.74 The Caldwell-Luc procedure. Intraoral incision is carried out along the alveolar ridge. The mucoperiosteum is then detached and retracted sufficiently. (a) The bony opening (perforation into the sinus) is made approximately 1 cm above the root apices of the first premolar using a small gouge, and then is enlarged by adequate instruments (e.g. Kerrison punch) until it is large enough. (b) Surgical instruments are inserted through this bony opening and necrotic tissues, granulation, and the diseased antral mucosa are peeled off and totally removed. Great attention is required to prevent injury of the infraorbital foramen, the nerve and vessels around the eye, and dental root apices. Then a new opening for drainage through the nose is created. Initially a piece of gauze with adrenalin should be inserted into the nose or 1/80 000 epinephrine is injected into the nasal mucosa in order to prevent excessive bleeding. A hole is made in the thin nasointral bone of the inferior nasal concha using a small gouge or osteotome, leaving it attached only at the floor side so that it can be folded into the antral cavity. (c) After the nasal mucosa is cut and removed, creation of an opening from the antrum to the nose is confirmed. The hole is enlarged sufficiently using rasps and other instruments. (d) After careful inspection of the entire field of operation, a long and thick strip is inserted into the antrum from the nose to maintain the entire width of the nasointral window. (e) Finally, the oral flap is closed and sutured.

of recovery, greater blood loss, and increased postoperative pain and facial swelling compared with endoscopic sinus surgery. In addition, resulting sinus scarring may be associated with recurrence; the procedure may also cause injury to the nerve responsible

for sensation to the maxillary skin and result in permanent disturbance of the natural function of the sinus lining. The Caldwell-Luc procedure should not be used in children as it seriously affects the normal growth of the maxillary sinus.

Endoscopic sinus surgery

Endoscopic sinus surgery uses fiberoptic technology. The endoscope is a very thin fiberoptic instrument, which visualizes the antral condition with minimal surgical wounding. This surgery is performed entirely through the nostrils, leaving no external scars. Its goal is to open the natural drainage channels, restoring normal physiologic function of the sinus mucosa. Materials blocking the sinus openings and any foreign bodies are removed using surgical instruments that are inserted alongside the endoscope. There is little swelling and only mild discomfort after surgery. As this operation needs special medical instruments and careful surgical technique, it should only be performed by an appropriate specialist.

Adjunctive treatments**Surgical removal of foreign bodies from inside the maxillary sinus**

Any foreign body displaced into the sinus cavity must be surgically removed. Small foreign bodies, such as teeth, root tips, broken instrument fragments, and dental implants, can be retrieved with small forceps, or the use of suction through the expanded extraction socket or a small bony opening that is intentionally created in the canine fossa (Fig. 29.75). On the other hand, if such procedures are difficult, the Caldwell–Luc operation may be required. It is important initially to locate any foreign body in the sinus using radiographic analysis.

After removal of any foreign bodies, the sinus cavity should be washed with saline to reduce risk of contamination, and antibiotic therapy should be administered to prevent infection, even if there is not unequivocal evidence of infection in the antral cavity and wound.

Surgical closure of oroantral communications

Extraction of the tooth sometimes induces an oroantral communication. The defect usually closes spontaneously with normal blood clot formation and routine mucosal healing. However, if the defect is large or persists for a long period, it may not heal spontaneously and may need surgical closure (see the later section, Oroantral communication and fistulae).

Influence of non-odontogenic maxillary sinusitis on the teeth

As maxillary premolar and molar teeth are located close to the floor of the sinus, non-odontogenic sinusitis can affect these teeth. Its influence ranges from mild and reversible irritation in the pulp and periodontal ligament to significant damage that may cause irreversible pulpitis and pulpal necrosis. If the patient has a toothache in teeth with no apparent dental disease, and any symptoms possibly associated with sinusitis such as a stuffy nose, involvement of non-odontogenic maxillary sinusitis may be suspect-

ed. Diagnosis and treatment should be carried out with collaboration between the dentist and a specialist (otolaryngologist).

Fungal sinusitis (*Aspergillus* mycetoma of the maxillary sinus)

Occurrence of fungal infection (mycosis) in the paranasal sinuses is relatively rare. The vast majority of cases involve *Aspergillus* species. *Aspergillus*-associated sinusitis is also called *Aspergillus* mycetoma of the maxillary sinus, aspergilloma or mycetoma of paranasal sinus. *Aspergillus* species are opportunistic fungi and widely distributed in the environment.

The majority of *Aspergillus*-associated sinusitis cases are unilateral.¹³² The disease usually occurs in adult patients with a female predominance.¹³³

Amongst members of *Aspergillus* species, *Aspergillus fumigatus* is the most common isolate.¹³² Although the exact etiology of *Aspergillus*-associated sinusitis remains unclear, the disease is believed to result from opportunistic entry of the fungus into the sinus or due to iatrogenic circumstances. Previous over-extension of the root canal sealer into the maxillary sinus during root canal treatment is thought to be an etiological factor, as treatment materials are known to carry the fungus.¹³⁴

The disease can be divided into two clinical forms, non-invasive and invasive. The non-invasive form may be seen in immunocompetent patients, whilst the invasive form usually occurs in hosts with an immunodeficiency. The majority of *Aspergillus*-associated sinusitis is non-invasive. In the case of the non-invasive form, a “fungal ball” may form within the affected sinus. The common clinical presentation is not specific, with various symptoms such as nasal obstruction, purulent nasal discharge, facial pain, and a chronic cough. Thick, tenacious, dark secretions may be characteristic signs. Some cases are asymptomatic, and, in these, the disease is often detected accidentally following radiographic study during routine dental treatment. In contrast, the invasive form may induce serious symptoms such as ophthalmoplegia, ptosis, frontal hypoesthesia, postorbital pain, and visus abnormalities, resulting from spreading to the orbit and skull. The prognosis of the invasive form can involve serious sequelae or even death.

Calcifications in the affected sinus may be seen on plain film radiography or in CT scans (Fig. 29.76). In the case of invasive form, bony destruction is also evident. Differentiation from maxillary sinus carcinoma is required. Culture of clinical specimens often does not result in the isolation of *Aspergillus*, and in many cases, diagnosis is made with pathological examination of a specimen obtained by biopsy or debridement.

It is necessary to surgically remove thick, dark, greasy materials (the sinus fungal masses) and to ensure the establishment of adequate sinus drainage

Fig. 29.75 A foreign body displaced into the antral cavity can be retrieved with small forceps and with the use of suction through the expanded extraction socket or a bone opening created in the canine fossa. (a) If the dental root or foreign body is displaced from extraction socket, the socket may be enlarged buccally after elevation of a mucoperiosteal flap to expose the maxilla above the socket. If this is difficult or inapplicable, an opening in the canine fossa should be made as follows. (b) A mucoperiosteal flap is made around the canine–premolar recess. (c) After the flap is reflected, a new small oronasal opening is created in the bone, 1 cm above the root apices of the first premolar. (d) Saline solution is injected into the antral cavity to flood the sinus through the expanded socket or the opening and then a suction tube is inserted. The foreign body is likely to be sucked out together with saline solution or moved close to the opening for easy retrieval. After removal of foreign body and irrigation of sinus using saline, the wound is primarily closed. Use of short-term prophylactic antibiotic is recommended.

and aeration via the Caldwell–Luc procedure or endoscopic sinus surgery. There is little tendency of infection recurrence after successful removal of the fungal masses and the use of systemic antifungal therapy for the non-invasive form is generally unnecessary. However, the invasive form may require the use of systemic antifungal therapy after debridement.

Oroantral communication and fistula

An oroantral communication is an abnormal connection between the oral and antral cavities. Various factors such as cysts, trauma, tumors, and even minor dentoalveolar surgical procedures can be involved in this pathogenic condition. The extraction of the maxillary posterior teeth, however, is the most common cause, because of the anatomically close relationship between the root apices and the maxillary antrum, and the thinness of the antral floor in that region. Despite discrepancies between studies, the maxillary second molars have been reported to be the teeth closest to the base of the sinus.¹³⁵ The root apices of these teeth are separated from the floor of the sinus by only a thin bony lamella and antral mucous membrane. In extreme cases, only the mucous membrane exists between the roots and the sinus floor, with a lack of bony intervention. Periapical infection destroys the bone near the floor of the maxillary sinus and it raises the risk of oroantral communication resulting from extraction of the tooth.

If oroantral communication is left open, epithelial tissue may develop in its track. As previously described, such a situation is defined as a fistula. Oroantral communication can close spontaneously, although once a fistula is established, it usually does not heal without surgical intervention.

Saliva harbors a large number of bacteria. Unlike oral mucosa, the antral mucosa is sensitive to salivary contamination. A long-standing oroantral communication or fistula provides the constant exposure of antral mucosa to saliva and other oral contaminants. Therefore such a condition substantially raises the likelihood of antral infection and its recurrence. The duration and width of the lumen of the fistula canal generally correlates with the likelihood of sinusitis,

Fig. 29.77 Oroantral fistula. The defect is covered with granulation and epithelium, but a small defect is seen on careful inspection.

although infection of the sinus is possible in a short period and with a very narrow fistular canal.

Clinical findings and diagnosis

Clinical symptoms of oroantral communication and fistulae are similar. Common symptoms include an unpleasant tasting discharge and odor, reflux of fluids and foods into the nose from the mouth, leakage of air, and difficulty in tobacco smoking. The presence of these symptoms can be indicators for diagnosis, although some patients remain asymptomatic.

In the case of a new oroantral communication created by tooth extraction, osseous defects and communication between the mouth and antrum may be confirmed by careful visual inspection with a dental mirror and good light. Since hemorrhage at the surgical site often obscures visibility, inspection should be performed after hemostasis. Gentle suctioning of the socket may produce a hollow sound that again is an indicator for diagnosis. It is of value to ask whether the patient feels leakage of air when blowing against the closed nostrils. Probing is generally not recommended because insertion of an instrument into the antral cavity itself can cause the antral perforation, and may also bring oral contaminants into the sinus.

In the case of a long-standing oroantral fistula, the fistular tract is often filled with granulations and epithelium (Fig. 29.77). Therefore careless visual inspection may not detect the defect. Gentle probing using a sterile and fine instrument with blunt tip is advocated if the presence of an oroantral fistula is suspected.

Radiographs assist in diagnosis and are useful to assess the size of defect, whilst it is difficult to determine if the oroantral tract actually is present using only a radiograph.

Management of oroantral communication

Although the antral mucosa is less tolerant of bacterial contamination, the sinus mucous membrane does have a local defense system. Therefore sinus exposure

or perforation does not always lead to the onset of sinusitis. Nevertheless, adequate treatment is necessary to reduce the risk of sinusitis if an oroantral communication is present.

The prime purposes of management are the closure of the defect and prevention of the sinusitis involving oral contaminants. Strategies for specific cases are described below. The patient should be carefully monitored and should be assessed often if the oroantral communication or fistula has closed, and assessed for any indication of maxillary sinusitis presence until healing of the defect is evident.

Oroantral communication created during endodontic therapy

Overfilling around the root apex of the maxillary teeth during routine endodontic treatment may cause a communication between the mouth and sinus via the root canal. If the root canal is not infected and is filled properly, the risk of sinusitis is considered minimal with no requirement of additional prophylactic procedures. However, if the root canal is infected, use of a short-term prophylactic antibiotic is advocated. Special care should be taken not to cause leakage of infected materials and any irrigation solution into the antral cavity through the root canal during endodontic therapy.

In the case of acute odontogenic sinusitis, the root canal of a causative tooth is available for drainage. If the tooth is salvaged, filling of the root canal should be performed after elimination of infection in the sinus.

Oroantral communication created during tooth extraction

Despite the performance of an adequate surgical technique, oroantral communication often occurs as a result of extraction of maxillary teeth. The treatment plan for avoiding sinus exposure or perforation should be made beforehand with evaluation of radiographs. Periapical and panoramic radiographs are available to assess if the patient has an excessively pneumatized sinus or widely divergent or dilacerated roots, which are risk factors of oral communication after the surgery.

If an oroantral communication is created, immediate and spontaneous closure of the opening by normal blood clot formation and routine mucosal healing usually occurs. Oroantral communication may not heal spontaneously if the osseous defect is large. It has been reported that if the diameter of the opening is greater than 5 mm, spontaneous healing may not occur and surgical intervention is required.^{136–138}

A less invasive treatment should be considered initially. Sutures to hold the wound edges closed are of value as an initial attempt, reserving closure with the flap technique, if the opening is not large. A relaxing incision in the gingiva around the opening is often

helpful to hold the wound edges closed and to reduce mucosal tension resulting from sutures. Additional application of a temporary appliance (such as a periodontal pack) to cover the defect is also useful to prevent the entry of food into the sinus, but it must not be inserted into the defect. Prescription of an antibiotic for prevention of sinusitis is recommended.

In contrast, immediate surgical closure with the flap technique may be necessary if the defect is sufficiently large that the surgeon feels that it may not heal by suture or other less invasive techniques.

The presence of sinusitis prevents healing of oroantral communication and fistulae. Therefore, it is imperative to eliminate antral infection before surgical closure. Conservative treatments include frequent irrigation of the fistula and use of antibiotics and decongestants. Surgical closure is available together with the Caldwell–Luc procedure or endoscopic sinus surgery.

Oroantral communication created during dentoalveolar surgery

If a small antral perforation is made accidentally or iatrogenically during a surgical procedure (e.g. removal of a cyst in the maxilla, excision of a tumor from the maxillary alveolar process, sequestrectomy, apicectomy of maxillary teeth or drilling in implant surgery), then foreign body retrieval, antral irrigation with sterile saline, and immediate primary wound closure are all necessary. Flaps should be closed and sutured tightly without excessive tension on the flaps and surrounding tissues. A drain must not be used because it can be a source of saliva contamination. In cases where the defect cannot be covered without tension using the original flap, surgical closure of the defect using a buccal or palatal flap should be considered. If the defect is extremely large and cannot be covered with these flaps, graft operation or use of a prosthesis is indicated. Prescription of an antibiotic following the operation is recommended.

Management of oroantral fistulae

As described previously, an oroantral fistula usually persists for a long period and does not close spontaneously. Consequently, surgical closure is a necessity regardless of defect size. Also, a long-standing oroantral communication that has been present for 4 weeks or longer is unlikely to heal spontaneously and needs a similar treatment to that provided for an oroantral fistula.¹³⁶

Unlike a fresh oroantral communication, the osseous defect surrounding the fistula is usually larger than the clinically apparent, soft tissue deformity. Moreover, because polypoid mucosa and epithelialized, infected or degenerated tissues in and around the fistula must be removed, the soft tissue defect may become larger. Therefore, it may be difficult to

close the defect by suture alone and surgical closure with the flap technique is then a necessity. The most common techniques are the buccal and palatal flap methods.

Closure should not be undertaken if there are foreign bodies lodged in the alveolus or the floor of the sinus. Removal of foreign bodies and ensuring a disease-free sinus are necessary prior to surgical closure.

In the case of an unsuccessful closure of an oroantral fistula by multiple surgical procedures or where there is a long-term persistent fistula, significant inflammatory changes in the sinus mucous membrane may result. In these cases, surgical closure and radical operation for the sinusitis should be performed concomitantly.

Surgical closure with the flap technique

Surgical closure of oroantral communications with the flap technique is performed either immediately after the opening is created or later, as in the case of a long-standing fistula or failure of an attempted primary closure. Although many surgical techniques have been proposed, traditional techniques using buccal advancement and palatal flaps are still widely used. The factors that should be considered for choice of each technique include whether the defect is a new oroantral communication or fistula, the location and size of the defect, the anatomic relationship between the defect and the neighboring teeth, the height of the alveolar ridge, duration of sinus exposure, the pres-

ence or absence of infection in the sinus, and the general health status of the patient.

Any surgical technique requires adequate flap design. The flap should have a broad base and margins that will be positioned over bone but not directly over the defect area of the communication, and it should not be under tension when in position.

Buccal advancement flap technique

The buccal advancement flap technique is a simple, easy and relatively non-invasive procedure (Fig. 29.78). However, it does require careful manipulation and flap design, because the flap is thin and has limited mobility. The technique is used primarily for closure of a minor alveolar communication and it is not the preferred method for large communications or recurrent fistulae. Inclusion of the buccal pad of fat increases the use of this technique.

The simplicity, ease of technique, and resulting low intensity of postoperative pain and discomfort are the major advantages of the method. It is particularly suitable in cases where the defect appears buccally in the depth of the vestibule and where the buccal flap has already been raised. However, this buccal flap technique has the following disadvantages. Firstly, the possible extent of coverage by flap is limited due to a narrow donor site and limitation in flap mobility. This technique is unsuitable for closure of a large defect. Secondly, because the flap is thin, wound dehiscence might occur after the operation. Thirdly, this technique may result in a loss of vestibular depth, which can interfere with prosthodontic

Fig. 29.78 The buccal flap procedure for oroantral communication and fistula. The first thing that should be done is excision of the fistula if presented. (a) The flap design is made. The flap margins should be wide enough to rest on the bone and when advanced, to cover the osseous defect. It is also important to make a broad base in the flap to ensure adequate blood supply to the flap. An incision of the periosteum near the base of the flap is essential to permit advancement of the flap. (b) Flap mobility can be improved by undermining the periosteum at both flap (buccal) and palatal sides. The flap is released to the depth of the buccal vestibule. (cont'd)

Fig. 29.78 (cont'd) (c) If necessary, the top buccal and palatal margins of the alveolar bone can be arranged to reduce the flap tension. (d) The buccal flap is pulled over the alveolar defect and fastened to the palatal gingiva by sutures. Interrupted sutures may be used to close the two buccal incisions to hold the flap.

Fig. 29.79 The palatal flap procedure for oroantral communication and fistula. The clinician must know the anatomy of the greater palatine vessels beforehand. The fistula should first be excised if presented. In the case of the fistula, as the entire tract may be epithelialized, a funnel-shaped tissue section is removed down to the alveolar bone. (a) Following this procedure, the flap is then designed. As the palatal mucosa is not very elastic, a meticulous flap design is required. If the flap is adequately designed, it should extend forward sufficiently on the palate to allow flap rotation to cover the defect. Great attention during flap construction is required to prevent injury of palatine vessels and resultant hemorrhage. (b) The flap tissue is detached from the palate with the periosteum and it should contain blood vessels. A small V-shaped excision can be made at the area of the greatest bend of the flap to prevent folding and wrinkling at the base and also to allow easier rotation of the flap. The gingiva on the buccal side of the alveolar process is undermined with a periosteal elevator to facilitate the penetration of the entire thickness of the mucosa by the suture. (cont'd)

rehabilitation and maintenance of oral hygiene. Finally, subsequent postoperative scarring may cause impaired mobility of the oral mucosa around the flap donor site.

The palatal flap technique

The palatal flap harbors the greater palatine vessels that provide a rich blood supply to the flap (Fig. 29.79). This technique involves mobilization and rotation of large mucosal flaps to cover the osseous defect with soft tissues, the margins of which are sutured over.

The advantages of this method over the buccal flap method include: (1) provision of more tissue attachment without tension, which promotes healing and resists the tendency of the flap to return to its original position; (2) use of a flap that is firmer and more resistant to trauma and infection; (3) a broad spectrum of indication, including cases with large bone defects; and (4) preservation of the maxillary vestibular sulcus depth. In contrast, this method has several disadvantages including: (1) denudation of the palatal surface; (2) probably greater postoperative pain; (3) it is a relatively complicated technique that may require extensive clinical experience of the surgeon; (4) the later appearance of roughness and deepening of the donor area, resulting from secondary epithelialization; (5) possible flap necrosis; and (6) interference with wearing of a partial denture that covers the hard palate. This technique is rarely used now.

Postoperative care and possible major complications

The strict cooperation of the patient during the postoperative period is a necessity. Clinicians should ask the patient to avoid any action that causes suction in the mouth (e.g. the use of a drinking tube, drawing on a cigarette or pipe), or produces pressure in the nose, such as vigorously blowing the nose or sneezing.

Fig. 29.79 (cont'd) (c) The flap is rotated and then advanced to attach to the gingival edge of the buccal side. A properly designed flap generously covers the entire gingival excision wound, which should be larger than the perforation of the bone. The flap is then sutured to the gingiva of the buccal side. The donor site forms a deep wound into which a piece of iodoform gauze is tightly packed, to prevent the flap from returning to its natural location and to relieve the tension on the suture. Alternatively, the palatal split (that should be made in advance) is adapted.

In the case of the palatal flap procedure, the dressing should be left in place for 3–5 days. There should be frequent evaluation of the patient's condition, wound, flap, and antrum; adequate treatment is required until the evidence of healing is seen. If the flap breaks down, it is often due to a poor blood supply arising from improper flap design, excessive suture tension or infection.

Consideration for antibiotic prophylaxis and its regimen

The maxillary sinus can be contaminated with the oral microflora that may invade the antrum through the oroantral communication or fistula. Moreover, the flap may be sensitive to the infection because the blood supply to the flap is not very rich. Therefore, the use of systemic antibiotics is recommended to reduce the risk of infection. The pathogens involved in possible infection tend to be viridans streptococci and anaerobes. Amoxicillin (250 mg 8-hourly) or erythromycin (250 mg 8-hourly) prescribed for 1–5 days is therefore recommended.

Peritonsillar abscess

A peritonsillar abscess is an abscess formed in the peritonsillar space that lies between the tonsil and the pharynx. It is most common in young adults (persons 20–40 years of age), but is rare in children.

Etiology and pathogenesis

Peritonsillar abscess usually results from a complication of acute tonsillitis that has been untreated or partially treated. Other causes include mucosal injury to the tonsil and extension of infection in the third molar.

A collection of pus is usually seen 4–7 days after onset of infection. If the superior constrictor muscle is penetrated, an infection of the lateral pharyngeal space may result, raising the risk of serious complications (Fig. 29.80). In severe cases or bilateral abscesses, the oral airway may be reduced. Although peritonsillar abscesses generally respond well to treatment, approximately 10–15% of patients have recurrence after resolution of the original abscess.¹³⁹

Microbiology

Most abscesses show a polymicrobial profile, consisting of both aerobic and anaerobic organisms. The

Fig. 29.80 Peritonsillar abscess is located in close proximity to the lateral pharyngeal space and separated only by the superior constrictor muscle. Therefore infection can extend to the lateral pharyngeal space.

most prevalent bacterial isolates from peritonsillar abscesses include *Streptococcus pyogenes*, *Staphylococcus aureus*, *Haemophilus influenza*, and species of strict anaerobic bacteria (e.g. *Fusobacterium*, *Prevotella*, and *Peptostreptococcus*).⁹⁴

Clinical features

The lesion is commonly seen unilaterally with edema and erythema of the tonsils (Fig. 29.81) and causes extreme soreness of the throat, odynophagia, persistent pain in the peritonsillar area, often radiating to the ear and neck, otalgia, and trismus resulting from the pterygoid muscles. The uvula may be displaced towards the unaffected side. Drooling and salivation, and trouble handling oral secretions may result. Neck pain associated with tenderness or when rotating the neck, swollen lymph nodes, and breath malodor are also common. Infection often affects the patient's speech resulting in so-called "muffled voice" or "hot potato voice" (sounds like the patient is talking with hot food in the mouth).

As the infection progresses, a range of systemic symptoms including fever, malaise, and headache may appear. As with other acute infections, increased leukocyte count and CRP level are evident on blood examination.

Diagnosis

Diagnosis is relatively easily made through the patient's medical history and a physical examination. The use of a CT scan and ultrasonography is useful for a determinative diagnosis and in identifying abscess formation (Fig. 29.81). The collection of pus from the abscess through needle aspiration is often considered to be the gold standard for diagnosis of peritonsillar abscess.

Differential diagnosis with odontogenic infections, especially pericoronitis, salivary gland infection, peritonsillar cellulites, lateral pharyngeal infection, and neoplasms (including lymphoma) is required. A thorough intraoral inspection and the patient's

Fig. 29.81 Edema and erythema of the tonsils and peritonsillar area. A CT scan (right) demonstrates the formation of an abscess.

medical history are useful to rule out infection of the salivary glands and odontogenic infection. In contrast with peritonsillar abscess, lateral pharyngeal infection may also induce swelling in the lateral aspect of the neck.

Treatment

Treatment of peritonsillar abscess requires both administration of antibiotics and surgical drainage. Incision and drainage are the essential aspects of treatment. As vital structures are located around a peritonsillar abscess, care should be taken during needle aspiration and incision.

The choice of antibiotics should depend on the result of microbiologic examination of the clinical specimen obtained by needle aspiration. Penicillin has been the traditional antibiotic of empiric choice. However, due to an increased prevalence of penicillin-resistant bacteria, mono-antibiotic therapy with penicillin may be inadequate. If microbiologic data is unavailable, a regimen consisting of oral penicillin and metronidazole is recommended.¹⁴⁰ Alternatively, oral clindamycin, second- or third-generation cephalosporins or quinolones may be effective. In severe cases or in immunocompromised patients, intravenous administration of either or both of imipenem and clindamycin may be advocated. For prevention of recurrence, an additional course of oral antibiotic should be taken for 7–10 days after the infection has clinically resolved.

Suppurative arthritis of the temporomandibular joint

The occurrence of suppurative (septic) arthritis of the temporomandibular joint (TMJ) is rare and usually associated with depression of host defense mechanisms.

Suppurative arthritis takes either an acute or chronic form. Acute infection has the potential to extend extensively, especially to the temporal space, often resulting in serious complications. Aggressive or long-standing infections cause significant destruction of the components of the TMJ, which is associated with functional sequelae including disturbances of jaw growth, fibrosis, and ankylosis of the joint; the latter is the most common complication. Once the infection becomes chronic, the disease may become long-standing and unresponsive to treatment. Therefore, early diagnosis and timely treatment are a necessity.

Etiology, pathogenesis, and microbiology

Suppurative arthritis of the TMJ may result from direct extension of an adjacent infection such as osteomyelitis of the jaw, tympanitis, traumatic or sur-

gical wound infection of the TMJ or hematogenous dissemination of bacteria from a distal site secondary to a systemic process. Staphylococci and streptococci are predominant isolates.^{141,142}

Clinical signs and symptoms

Suppurative arthritis of the TMJ usually manifests unilaterally. Common clinical signs of acute arthritis are preauricular edema with heat and pain, trismus, malocclusion, and contralateral mandible deviation resulting from the increased joint fluid. Patients may present with regional lymphadenopathy, malaise, and fever. In the chronic form, swelling and pain may be minimal but trismus and malocclusion are evident.

Diagnosis

Diagnosis must be made rapidly to prevent permanent joint damage. Diagnosis is made based on the patient's medical history, local signs and symptoms, any adjacent infection, laboratory testing, and imaging. Aspiration from the joint is helpful to confirm the diagnosis and to identify the causative organism. Imaging studies (plain X-ray, CT scan or MRI) may show joint space widening and anterior/inferior displacement of the condylar head (Fig. 29.82). Bone destruction is not seen in the early stages but may appear in the case of longer-standing infections. Arthroscopy allows direct visualization of the joint cavity.¹⁴¹ Arthroscopic features include a reddened and swollen synovial membrane that can sometimes appear necrotic, exhibit bleeding, and have a proliferation of synovial villi, and a degenerative-appearing periosteum exposing the bone of the glenoid fossa.

An elevated leukocyte count and increased CRP levels may be evident in the acute phase of the infection.

Differential diagnosis is required from TMJ disorder, fractures, acute parotitis, osteomyelitis, rheumatologic disease, condylar hypertrophy, and neoplasm.

Fig. 29.82 Patient with chronic suppurative arthritis of the temporomandibular joint. Trismus and contralateral mandible deviation are seen. MRI demonstrates an inflammation of the temporomandibular joint and surrounding tissues.

Treatment

Treatment includes antibiotic therapy, aspiration and drainage of pus and infected synovial fluid by incision, proper hydration, pain control, and restriction of jaw movement. Although parenteral penicillin G is adequate as a drug of empiric choice, selection of an antibiotic should be made on the basis of culture and sensitivity testing. Prolonged administration of an antibiotic is recommended to prevent recurrence. Once infection has been controlled, physical therapy should start to improve the mandibular range of motion and deviation on opening movement. Early rehabilitation exercises are also necessary to avoid fibrosis and ankylosis of TMJ.

Long-standing infections with significant pathogenic changes and destruction of the joint may necessitate condylar surgery.

Actinomycosis, tuberculosis, and syphilis

Actinomycosis, tuberculosis, and syphilis are uncommon and present unique lesions that are characterized by chronic granulomatous inflammation. The etiology, pathogenesis, and microbiology are different between the conditions.

Actinomycosis

Actinomycosis in the maxillofacial region is uncommon. It is characterized by a chronic granulomatous process with formation of one or multiple abscesses and indurated swelling of the soft tissue (Fig. 29.83). On rare occasions, the infection localizes in the bone, causing actinomycotic osteomyelitis, although this is not included in the remit of this section. Although actinomycosis may occur at any age, it most commonly occurs between 20 and 60 years of age and cases in men are the most prevalent.¹⁴³

Actinomycosis is distinct from other types of orofacial infections. Odontogenic infections and other orofacial bacterial infection sometimes yield

Fig. 29.83 Patient with mandibular actinomycosis. Indurated swelling with fistulae on the skin is evident.

Actinomyces species, but these are distinct from actinomycosis.

Aetiology and pathogenesis

Since the virulence of *Actinomyces* species is low, the exact etiology and pathogenesis of actinomycosis remains unclear. However, poor dental hygiene, occurrence of surgical procedures within the mouth, oral trauma, odontogenic infection, chronic mastoiditis, chronic otitis, and chronic tonsillitis are associated with its occurrence.^{143–145} These factors may play a role in the invasion of *Actinomyces* into deeper tissues by a break in the mucosal barriers and thus causing an enhancement of bacterial pathogenicity.

Microbiology

Actinomyces species are pleomorphic non-spore-forming and non-acid-fast anaerobic Gram-positive bacilli.⁹ *Actinomyces* species are members of the commensal flora of the mouth. Actinomycosis is primarily caused by *Actinomyces israelii* but *Actinomyces naeslundii*, *Actinomyces viscosus*, *Actinomyces gerencseriae*, *Actinomyces graevenitzii*, and *Actinomyces meyeri* can also be involved.^{143–145} The infection is usually polymicrobial with other oral commensal bacteria, especially anaerobic Gram-negative bacilli, often isolated from the infection (Fig. 29.84).

Clinical features

Actinomycosis commonly occurs in the soft tissue of the mandible, especially around the third molar and

Fig. 29.84 Microscopic view (a) of pus obtained from a patient with mandibular actinomycosis and (b) the isolated bacterial colonies on an agar plate. The arrows indicate cells (a) and colonies (b) of *Actinomyces israelii*. Photographs courtesy of Dr A. Kanekawa (Yamaguchi Grand Medical Center).

the mandibular angle. It may present in either an acute or chronic form, with the latter being the most common.

Initial clinical signs and symptoms of chronic actinomycosis are similar to those of common suppurative infection. As the swelling increases, enlarging tissues become indurated, which can manifest as tumor-like masses. There may be no fever associated with this inflammatory mass. The surface of the skin overlying the jaw becomes rough and has a reddish-brown discoloration. In the case of actinomycosis in the posterior mandible, the infection is likely to affect the masticatores and cause a resultant trismus. Unlike other infections, actinomycosis does not follow the usual anatomic planes and tends to erode and to burrow through them. Infection occasionally spreads to involve the bone. The lesions of actinomycosis enlarge slowly with minimal elevation of temperature and little pain. Over time, abscesses form within firm swellings with the development of multiple fistulae on the skin. The amount of pus or exudate from each abscess tends to be small and any exudate often contains sulfur granules (Fig. 29.85), which are collections of microcolonies of the organisms. The fistulae may persist for long periods or close spontaneously, but even when they close, new tracts may quickly develop. Chronic actinomycosis may persist or recur over weeks, months or even years. A pattern of remission and exacerbation may characterize the disease. Patients often have a history of multiple episodes of recurrent infection, which initially respond well to antibiotic therapy but recur after antibiotic therapy stops.

There is no characteristic marker of actinomycosis in blood specimens and the leukocyte count is often normal or only minimally elevated.

The acute form of the infection causes a painful and fluctuant swelling that resembles or mimics acute odontogenic infection, with a range of elevated body temperature.

Diagnosis

Diagnosis of actinomycosis, and especially differentiating it from pyogenic infection, may be difficult. Therefore, diagnosis is usually made based on the consideration of all factors, including clinical signs and symptoms, the patient's medical history, the presence of sulfur granules, and microbiologic findings.

Fig. 29.85 Sulfur granules originating from a pus specimen. Photograph courtesy of Dr A. Kanekawa (Yamaguchi Grand Medical Center).

The detection of sulfur granules either macroscopically or microscopically is a characteristic finding but it is not usual. If a patient exhibits indurated swelling with multiple fistulae and trismus (if disease affects the masticatores) and a history of recurrent or late infection after tooth extraction, actinomycosis should be considered. The microbiologic examination of clinical specimens provides significant information for diagnosis. It is important to note that the growth of *Actinomyces* colonies on culture media is slower than that of other anaerobic bacteria. Specimens should be incubated in an anaerobic environment for at least 10 days to obtain adequate results. Although isolation of *Actinomyces* from specimens can be definitive evidence for the diagnosis of disease, it should be remembered that *Actinomyces* culture-negative samples frequently occur in patients with actinomycosis. Conversely, *Actinomyces* isolation may result from contamination of the specimen with oral commensal bacteria. The results of microbial examination should therefore be interpreted appropriately and with caution.

Radiographs are non-specific for actinomycosis even in the presence of soft tissue swelling and fistula. CT scans may reveal loculations and dense fibrosis.

Differential diagnosis between actinomycosis and suppurative infection, orofacial tuberculosis, and neoplasms is essential.

Treatment

Actinomyces species are highly susceptible *in vitro* to various types of antibiotics including β -lactam antibiotics, macrolides, clindamycin, and tetracycline. However, highly fibrous tissues around lesions can prevent penetration of antibiotics to the infected area. Therefore use of higher doses of antibiotics and surgical intervention is necessary.

Surgical intervention includes frequent incision, drainage, and excision of all fistulae. The prime purpose of these procedures is to ensure the delivery of adequate amounts of antibiotic to the infected area and to reduce the levels of involved organisms by exposing them to air (oxygen).

Initial antibiotic therapy involves high-dose intravenous infusion of penicillin G (10–20 million U per day) for 3–14 days. The use of a prolonged course of antibiotic is required because the infection often recurs after short-term antibiotic use. After the initial course of antibiotic, additional oral antibiotic is administered for at least 3 months.

Other effective antibiotics include erythromycin, cephalosporins, tetracycline, clindamycin, and imipenem, but metronidazole and aminoglycosides are ineffective.

Tuberculosis

Tuberculosis is a serious infectious disease caused by mycobacteria, mainly *Mycobacterium tuberculosis*.⁹

Although tuberculosis most commonly attacks the lungs, it can also affect other organs including the central nervous system, the lymphatic system, the circulatory system, the genitourinary system, bones, joints, and the skin. The oral mucosa, skin of face, and lymph nodes are included as possible sites of tuberculosis lesions, and these usually manifest as secondary lesions of the disease.

Mycobacterium tuberculosis withstands certain disinfectants and survives in a dry state for weeks. Limited types of antibiotics are effective against this organism. An increased prevalence of multidrug-resistant strains of *M. tuberculosis* is now a serious public health issue in many countries, especially in developing countries.

Etiology, pathogenesis, and microbiology

Tuberculosis is one of the most prevalent infectious diseases in the world, particularly in developing countries. Infection is spread via droplets of sputum containing the acid-fast bacillus, *M. tuberculosis*, from patients with active pulmonary tuberculosis.

Clinical features in oral and maxillofacial regions

The classical intraoral presentation is an ulcer on the dorsal surface of the tongue but lesions may affect any site (Fig. 29.86). The ulcers are irregular with raised borders and often resemble deep fungal infection or squamous cell carcinoma. Tuberculosis can appear in the skin on the face around the nose and ears as lupus vulgaris, which is characterized by painful reddish-brown nodules that tend to ulcerate and form scars.

Tuberculosis can attack cervical lymph nodes and painless swelling of lymph nodes may result. In the more advanced cases, fistulae associated with the lymph node lesions may appear. Some cases present as asymptomatic calcification in the cervical lymph node (Fig. 29.87), and may be discovered by a routine panoramic survey.

Fig. 29.86 Oral tuberculosis exhibiting an ulcer on the dorsal surface of the tongue.

Diagnosis

Mucosal biopsy should be undertaken to demonstrate characteristic granulomatous inflammation with well formed granulomata, Langerhans giant cells, and necrosis. Ziehl-Neelsen or Fite stains may be used to detect the tubercle bacilli. Microbiologic culture of suspected clinical material may also be useful in the diagnosis of tuberculosis, although specialized media and prolonged incubation are required for recovery of the organism, and it often gives false-negative results. Molecular microbiologic methods are also available to detect the organism and aid diagnosis.

Treatment

Localized treatment is not required because oral lesions resolve when systemic chemotherapy with rifampin, isoniazid or ethambutol is provided. Typically, combinations of these drugs are used. Instead of the short course of antibiotics normally used to cure other bacterial infections, tuberculosis requires much longer periods of treatment (around 6–9 months) to entirely eliminate mycobacteria from the body.

Syphilis

Syphilis is a curable sexually transmitted disease caused by the spirochete, *Treponema pallidum*. The disease primarily affects the genitals, but can induce lesions in the skin, mucous membranes, and many other parts of the body including the brain and heart. The initial discovery of penicillin resulted in a dramatic decline in the incidence of the disease, but the incidence of syphilis has recently begun to rise along with the incidence of HIV/AIDS. If left untreated, syphilis can lead to serious complications or even death. However, severe cases are now seldom encountered in many countries due to early diagnosis and treatment.

Fig. 29.87 Calcification in the cervical lymph node involved in tuberculosis.

Etiology and pathogenesis

Microbial transmission is usually by sexual contact, although congenital syphilis can occur via transmission from mother to child *in utero*. Iatrogenic transmission between clinician and patient is possible via exposed wounds on fingers and hands.

Clinical features of syphilis in oral and maxillofacial regions

The signs and symptoms of syphilis may occur in four stages consisting of primary, secondary, latent, and tertiary. The primary lesion appears within a few weeks after exposure. The primary lesion is referred to as a chancre and is characterized by the development of a firm nodule at the site of inoculation, which breaks down after a few days to leave a painless ulcer with indurated margins. A single chancre is typical, but there may be multiple sores. Cervical lymph nodes are usually enlarged and rubbery in consistency. The lesion of primary syphilis typically disappears without treatment within 3–12 weeks without scarring, but the underlying disease remains.

The signs and symptoms of secondary syphilis may begin 6–10 weeks after the chancre appears. Secondary syphilis is characterized by a macular or papular rash, febrile illness, malaise, headache, generalized lymphadenopathy, and sore throat. The oral mucosa is involved in approximately one third of patients. Oral ulceration, often described as “snail track ulcer”, develops. Mucous patches or opaline plaques may also appear in the mouth. These signs and symptoms may disappear within a few weeks or repeatedly recur for up to a year. Lesions of secondary syphilis are infective and dentists must take care to prevent cross-infection.

Patients with untreated secondary syphilis can develop the latent form many years after initial infection. In this stage, no symptoms are present, although even in these cases the disease may progress to the tertiary stage.

The tertiary stage begins years after the original infection. In this stage, the pathogen may spread, leading to serious internal organ damage and death. Neurological and cardiovascular problems are significant, with the former causing stroke, meningitis, poor muscle coordination, numbness, paralysis, deafness or visual problems, personality changes, and dementia. Cardiovascular problems include aneurysm and inflammation of the major artery and other blood vessels, and various valvular heart diseases. Two oral lesions are recognized in the tertiary form of syphilis: gumma in the palate and leukoplakia affecting the dorsal surface of the tongue.

A pregnant patient with primary or secondary syphilis may infect the developing fetus, resulting in characteristic congenital abnormalities (congenital syphilis). Infection of the developing vomer produces a nasal deformity known as saddle nose. The feature

of Hutchinson’s triad is a common pattern of presentation for congenital syphilis, and includes interstitial keratitis, deafness, and dental abnormalities involving notched or screwdriver-shaped incisors and mulberry molars.

Diagnosis

Diagnosis of syphilis is supported when dark-field microscopy of smears taken from either a primary or a secondary lesion reveals numerous spirochetes in size and form typical of *T. pallidum*. However, serologic investigation is the most reliable way of syphilis diagnosis from the late stages of primary infection onwards. It is important to note that routine laboratory culture of *T. pallidum* is problematic and can be unreliable.

Treatment

Treponema pallidum has remained sensitive over the years to penicillin, erythromycin, and tetracyclines, and indeed the most effective treatment of any stage of syphilis is intramuscular procaine penicillin. Patients should be monitored for at least 2 years and serologic examinations repeated over this period.

Complications of maxillofacial infections

Although infections at oral and maxillofacial sites are usually localized, they may have systemic effects and/or involve contiguous structures. As a consequence, a variety of complications can occur (Fig. 29.88). Although complications can develop in immunocompetent patients, they are more prevalent in immunocompromised patients. Since these complications are often serious and potentially life-threatening, early recognition and prompt treatment are a necessity. Although the definitive diagnosis and management are usually undertaken by a specialist, dentists must be well aware of the seriousness of complications and recognize their clinical features.

Airway obstruction

A compromised airway is the most common life-threatening complication of maxillofacial infections. It is particularly prevalent when an infection involves the submandibular and cervical spaces. In the complete absence of inspired oxygen due to an airway block, brain damage occurs within 3–5 minutes. If an airway problem is not serious, patients can be managed with expeditious surgical drainage and appropriate use of antibiotics. However, the clinician must be aware that such conditions can rapidly progress within a few hours and at any time. Patients with a risk of a compromised airway should be monitored

Fig. 29.88 Orofacial infections can cause serious complications. Such complications arise through spread of the infection either by direct extension or via the hematological route from the infection site in the oral and maxillofacial regions.

constantly and early intervention should be undertaken without delay.

The clinician must not overlook any indications of a compromised airway and examples of these are listed in Table 29.29. Signs of cyanosis and altered consciousness result from hypoxia, indicating an airway problem. The elevation of the floor of the mouth, difficulty to move or protrude the tongue, and the presence of trismus, limited ability to extend and flex the neck, dyspnea, dysphagia, dysphonia, tachypnea, and stridor are common manifestations of airway problems. An inability to breathe in the supine position, labored breathing, shortness of breath, and a sensation of a lump in the throat also suggest a possible airway problem. Pain on speaking and a change in the character of a patient's voice are all important indicators in determining an airway problem. The patient may assume a "sniffing" position, extending the neck and chest slightly forward as if smelling a rose. This maneuver straightens the upper airway, decreasing airway resistance and thus is a sign of a compromised airway.

Assessment of oxygen saturation level using pulse oximetry without administration of supplemental oxygen is useful in inferring the status of oxygenation. An oxygen saturation value $>97\%$ generally indicates respiratory sufficiency, whilst a saturation value $<94\%$ or a diminishing trend suggests the need for more urgent airway intervention. It should be remembered that, although administration of supplemental oxygen provides the patient with satisfactory oxygen

Table 29.29 Possible indications of a compromised airway.

Cyanosis and altered consciousness
Elevation of the floor of the mouth
Difficulty to move or protrude the tongue
Limited ability to extend and flex the neck
Labored breathing
Shortness of breath
Inability to breathe in the supine position
Assuming the 'sniffing' position, seen as an extension of the neck and chest slightly forward as if smelling a rose
Inability to sleep in the supine position
Unusual snoring whilst sleeping
Sensation of a lump in the throat
Pain on speaking
Change in the character of a voice
Oxygen saturation of less than 97% when measured by pulse oximetry
Trismus, dyspnea, dysphagia, dysphonia, tachypnea, and stridor

levels, it may mask the actual problem of the compromised airway and may provide a false sense of security.

Radiographic imaging, especially a CT scan, can help determine the extent of infection and any distortion of the airway. Except for the patient in acute or imminent respiratory distress requiring immediate airway management, the CT scan should be an important component of the evaluation and provides information pertinent to airway management.

Sepsis

As the definition of sepsis has been diverse, a standardized terminology is required to eliminate confusion. An American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference published consensus conference definitions concerning sepsis (Table 29.30).¹⁴⁶ Sepsis is termed as the clinical syndrome defined by the presence of both infection and a systemic inflammatory response. It is often confused with bacteremia or systemic inflammatory response syndrome (SIRS). Bacteremia is the presence of bacteria in the bloodstream, regardless of a provoked host inflammatory response. SIRS is a systemic inflammatory response that is triggered not only by infectious but also non-infectious conditions. The interrelationship between sepsis, bacteremia and SIRS is presented in Fig. 29.89.

Sepsis can progress to shock, disseminated intravascular coagulation multiple organ dysfunction syndrome, and eventually death. Sepsis is more common and dangerous in elderly, immunocompromised, and critically ill patients. In adult patients, sepsis is considered to be present if infection is suspected or proven and two or more of the following SIRS criteria are met: (1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$;

Table 29.30 Definition of sepsis and other associated terms.

Infection
Microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms
Bacteremia
The presence of viable bacteria in the blood
Systemic inflammatory response syndrome (SIRS)
The systemic inflammatory response to a variety of severe clinical insults
Sepsis
Toxic condition resulting from the systemic inflammatory response to infection

Fig. 29.89 The interrelationship between systemic inflammatory response syndrome (SIRS), sepsis, and infection.

(2) heart rate >90 beats/min; (3) respiratory rate of >20 breaths/min or partial pressure of carbon dioxide (PaCO₂) of <32 mmHg; and (4) leukocyte count of >12 000 cells/μl or <4000 cells/μl, or >10% immature (band) forms (Table 29.31).¹⁴⁶

Blood culture is important in demonstrating the presence of bacteria in the bloodstream and identifying involved microorganisms. However, blood culture often provides false-negative results. Although blood culture positivity supports diagnosis, if the above SIRS criteria are met then sepsis should be diagnosed regardless of results of the microbial examination.

Table 29.31 Diagnostic criteria for sepsis.

Infection is suspected or proven
AND
Two or more of the following criteria are met:
(1) Temperature >38°C or <36°C
(2) Heart rate >90 beats/min
(3) Respiratory rate of >20 breaths/min or partial pressure of carbon dioxide (PaCO ₂) of <32 mmHg
(4) Leukocyte count of >12 000 cells/μl or <4000 cells/μl, or >10% immature (band) forms

Mediastinitis

The mediastinum is the potential space between the pleural cavities. It contains the heart, the great vessels, the trachea and main bronchi, the esophagus, the thymus gland, connective tissues, and lymph nodes. Fascial planes connect the mediastinum with the neck.

Mediastinitis is inflammation of the mediastinum. Mediastinal involvement following a maxillofacial infection is rare, but, if it is involved, the mortality rate reaches 40–60% despite the use of antibiotics and surgical therapy. A late recognition of disease or an improper course of treatment will result in a poor prognosis for patients. Mediastinitis associated with maxillofacial infection generally results from an extension of an infection through the pretracheal fascia, the lateral pharyngeal space, and/or the retropharyngeal–danger spaces (Fig. 29.90).¹⁴⁷

Common signs and symptoms of patients with mediastinitis include fever, chills, a shortness of breath, chest pain, swelling in the neck, dyspnea and dysphagia. A CT scan can indicate the presence of purulence and aid in an early diagnosis (Fig. 29.91). Prompt incision and drainage or debridement and

Fig. 29.90 The routes of extension of infection from the oral and maxillofacial region to the mediastinum.

surgical airway management, usually by thoracic surgeons, is required.

Orbital cellulitis

Orbital cellulitis is caused by infection of the orbital soft tissues by extension of infection from periorbital structures (especially the paranasal sinuses), direct bacterial inoculation from accident, trauma or surgery, and hematogenous spread of infection.^{148,149} Odontogenic infections, maxillary osteomyelitis, and dental extractions are also possible origins of orbital cellulitis. The condition can progress rapidly and involve the loss of sight and fatal cerebral complications.

Orbital cellulitis typically begins with a painful and erythematous swelling of the eyelid. Patients may be systemically ill with severe orbital pain, fever, proptosis, conjunctivitis and chemosis, impaired movement of the eye, and signs associated with optic nerve damage (e.g. decreased visual acuity, visual field loss, problems with color vision). A CT scan is the most useful investigation for its diagnosis.

Cavernous sinus thrombosis

The cavernous sinus is a large collection of thin-walled veins creating a cavity bordered by the sphenoid bone and the temporal bone of the skull (Fig. 29.92). It lies within the skull, immediately behind each orbit, and contains the oculomotor nerve (cranial nerve III), the trochlear nerve (cranial nerve IV), the ophthalmic nerve and maxillary nerves that are the branches of the trigeminal nerve (cranial nerve V), the abducens nerve (cranial nerve VI), and the internal carotid artery. The purpose of the cavernous sinus is to drain blood from the brain and face back to the heart.

Cavernous sinus thrombosis is blockage of a large vein within the cavernous sinus by the formation of a blood clot. The usual cause is a bacterial infection that has spread from the paranasal sinuses, ears, eyes, nose, or skin of the face, but an abscess in the maxillofacial region may also be involved in the etiology.¹⁵¹ Contamination of the cavernous sinus due to direct extension or hematogenous dissemination of infection can result in thrombosis. The initial infection

usually involves one side but can easily spread to the opposite side through the circular sinus.

Abrupt onset of unilateral periorbital edema, headache, an inability to move the eye, photophobia, loss of vision, drooping eyelids, lacrimation, proptosis, chemosis, and retinal hemorrhages may all be evident. There may also be cranial nerve involvement, which results in ophthalmoplegia, periorbital sensory loss and impaired corneal reflex, ptosis, and dilatation of the pupil. Severe systemic illness with a high fluctuating fever, chills, headache, rapid pulse, and sweating can all occur.

The diagnosis of cavernous sinus thrombosis is made through imaging studies (sinus radiography, CT scan, and MRI), in addition to the clinical presentation. Cavernous sinus thrombosis can progress rapidly and even today has a high mortality rate. Aggressive medical and surgical treatment are therefore required.

Neurological complications

Despite being very rare, acute suppurative maxillary infection has the potential for brain and nervous system involvement. Common neurological complications include meningitis and brain abscesses. These may be derived from metastatic spread by means of the bloodstream or may develop from close proximity to thrombophlebitis. Signs and symptoms of neurological complications should be looked for and recognized as early as possible because of the risk of fatality.

The meninges are the membranes that cover the brain and spinal cord, and act as an extra barrier to infection. Meningitis is an infection of the meninges, and is the most common neurological complication resulting from infections of the oral and maxillofacial region.¹⁵² Initial signs and symptoms are not specific. Symptoms may include a constant generalized headache, confusion, drowsiness, a high temperature,

Fig. 29.91 Chest CT scan of a patient with severe lateral pharyngeal infection. The CT scan shows the presence of pleural effusion, indicating mediastinitis.

Fig. 29.92 The anatomy of the cavernous sinus. (Illustration was redrawn with permission from Kirikae I, Nomura K, editors, *Modern Otorhinolaryngology*, 10th edition. Tokyo: Nanzando, 2004.¹⁵⁰ Copyright © I. Kirikae and K. Nomura.)

stiffness of the neck, vomiting, stomach pain, rapid breathing, convulsions and coma. Kernig's sign (a strong passive resistance when an attempt is made to fully straighten the patient's leg when the hip is flexed at 90°) and Brudzinski's sign (a spontaneous flexion of both the knees and hips in response to passive flexion of the neck towards the chest) are frequent positive indicators of meningitis. Diagnosis is made on the basis of the symptoms and clinical signs, the culture of microorganisms from the blood, and analysis of cerebrospinal fluid through lumbar puncture.

Bacteremia produced during maxillofacial infections and invasive oral manipulations can instigate brain abscess, although the blood–brain barrier along with the immune response usually excludes bacteria that attempt to gain an entry into the cranial vaults. This event is, therefore, very rare.

Depending on the specific location of an abscess within the brain, systemic responses to infection can lead to an increased intracranial pressure and damage to the focal cerebral tissue. As a result, headache, fever, papilledema, drowsiness, confusion, convulsions, seizures, dysphagia, ataxia, visual-field deficits, hemiparesis (paralysis or weakness affecting one side of the body) or speech difficulties may appear. The diagnosis is usually established through MRI (Fig. 29.93). Single or multiple ring-enhanced lesions in the brain parenchyma are seen with gadolinium MRI. Diffusion-weighted MRI features of a brain abscess have a specific high signal intensity.

Infections of oral and maxillofacial wounds

Wounds can be divided into surgical and traumatic wounds. Surgical wounds occur in optimum conditions with anesthetic and operating theatre support. In contrast, traumatic wounds are generally accidental and arise under non-sterile conditions and, as a result, tend to be associated with much more serious underlying injury with a range of bacterial contamination.

The Centers for Disease Control and Prevention (CDC) has defined surgical site infections as those associated with surgical procedures that occur within 30 days of an operation, or within 1 year of an important procedure.¹⁵³ The CDC currently advocates the term “surgical site infection” instead of “surgical wound infection”. The infection of a surgical incision is distinct from the infection of a traumatic wound. However, infections of surgically treated traumatic wounds can be categorized as surgical site infections. Wounds associated with traumatic injury generally have a higher infection risk than wounds originating from surgical procedures alone.

Surgical site infections may provide not only physical discomfort with a prolonged period of wound healing but also elevated financial costs to the health care provider. Furthermore, as a result of wound infection there may be unacceptable functional and esthetic sequelae. In extreme cases fatality can occur.

Fig. 29.93 MRI of brain abscess (a) associated with left buccal abscess involved in acute periapical infection (b). Pus accumulation and edema in the right brain are seen. Viridans streptococci, *Prevotella* spp., and *Fusobacterium* spp. were recovered both from brain and buccal abscess. Photographs with permission from Miss T. Tanbo (Kanazawa University).

This section discusses the basic principles of prevention and management of wound infections.

Etiology and pathogenesis

Key requirements for the establishment of a wound infection are the presence of a sufficiently large bacterial inoculum with sufficient virulence, the availability of a suitable environment for bacterial growth, and the impairment of local and systemic host defense mechanisms. There are various factors which predispose to wound infection (Fig. 29.94). These factors can be divided into systemic, local, and technical.

Systemic factors

Immunocompromising factors are generally systemically related. The long-term receipt of corticosteroid therapy, administration of cytotoxic and immunosuppressive drugs, uncontrolled diabetes, alcohol abuse, malnutrition, malignancies, myeloma, and HIV are all examples of predisposing factors that reduce host resistance. Amongst these, diabetes is perhaps the most frequently encountered. The likelihood of infection does indeed correlate with fasted blood sugar level. The glycosylated hemoglobin test or hemoglobin A1c is used together with fasted blood sugar level when assessing the level of diabetes control over the past 1–3 months.

Local factors

The number and type of contaminating microorganisms are determinants for the risk of wound infection. Although surgery in the absence of aseptic methods does undoubtedly increase the risk of wound infection, even a surgical wound created under aseptic conditions can be contaminated. Wounds with a pre-

existing infection are more likely to be infected compared with infection-free wounds, due to the high number of bacteria present. The location of a wound is also important, as the quantity and type of bacteria in the normal microflora can vary between sites thus affecting the nature of initial infection. Perioral and oral tissues are generally resistant to the establishment of infection, whilst the maxillary sinus is not as tolerant of contamination.

Factors that interfere with normal wound healing mechanisms contribute to the risk of wound infection. These factors include the presence of foreign bodies and necrotic tissue, devascularization or ischemia of the wound and the presence of dead spaces.

Foreign bodies may be contaminants that serve as sources of infection. Moreover, they may be recognized as non-self and can induce chronic inflammation, which may provide suitable conditions for the overgrowth of pathogenic bacteria. Examples of foreign bodies include trapped food or debris, fragments of non-viable bone, environmental materials left in the wound, and contaminated implanted medical equipment (e.g. sutures, wire ligatures, metal mesh, and implanted screws or plates).

Necrotic tissue acts as a foreign body and inhibits the normal wound healing mechanism. Due to a lack of adequate blood supply, dead or dying tissue is often infected. In addition, such tissue may represent a source of nutrients for bacterial growth. Tissue devitalized due to chronic inflammation and previous radiotherapy is also susceptible to infection.

In a wound with impaired vascular flow or ischemia, the delivery of oxygen, nutrients, components of immunity, and administered systemically antibiotics may be impeded. Dead spaces and hematomas usually fill with blood and/or exudates. Host defense mechanisms and the effects of antibiotics are all

Systemic factors	Local factors	Technical factors
Depression of host defense mechanisms	• Certain location of wound • Pre-existing infection • Devitalized or necrotic tissue • Tissue with ischemia and devascularization • The presence of foreign bodies, hematomas or dead spaces • Type, cause and mechanism of injury in the case of traumatic wound	• Excessive operating time • Wide extent of surgical area • Procedure without aseptic surgery • Unnecessary tissue damage • Improperly designed flaps and incorrect placement of incision • Excessive external and internal pressure on a wound • Insufficient hemostasis • Inadequate management of a hematoma or dead space • Insufficient tissue debridement • Inadequate suture and retractor that may be involved in tissue ischemia • Instability of fracture fragments • Primary closure of infected wounds • Delayed treatment for traumatic wounds

Fig. 29.94 Factors affecting the likelihood of wound infection.

impaired due to a limited blood supply at such sites. The contents of these areas can again serve as an excellent nutrient source for bacterial growth. Moreover, infection at such sites can cause hypertension in surrounding tissues, which in turn induces an additional impairment of blood flow.

In traumatic wounds the likelihood of infection is influenced by wound size, configuration depth and location, and the mechanism and cause of injury.

Technical factors

The duration of the operation and extent of the surgical area all correlate with the likelihood of wound infection.¹⁵⁴ Although the exact reasons remain unclear, a long and extensive operation provides a greater opportunity of tissue drying, tissue trauma, and external contamination. An inadequate surgical technique predisposes patients to wound infection. Examples include unnecessary tissue damage through inadequate use of clamps, improperly designed flaps, creation of tissue tension, and associated tissue devascularization and ischemia caused by hematomas, edema or tight or incorrectly located sutures, and the use of contaminated instruments or medical equipment. Inadequate layered closure, postoperative hemostasis, and the lack of or ineffective drainage producing dead spaces are also factors. Furthermore, an instability of fracture fragments and resulting motion inhibits the natural healing process and increases the risk of infection.

Delayed treatment of traumatic wounds results in a depression of tissue vitality, increased wound desiccation, and morbid edema. These changes increase the likelihood of infection by promoting microbial redistribution, wound contamination, and growth of pathogenic organisms.

Microbiology

Most infections of surgical wounds are contaminated by the patient's own endogenous microflora present on the skin or mucous membranes. Therefore, the microbiology is largely determined by the location of the wound and the presence or absence of salivary contamination. However, sources of pathogens also include surgical/hospital personnel and intraoperative factors including surgical instruments, articles brought into the operative field, and the operating room air.

Infections of oral wounds usually involve viridans streptococci and anaerobic bacteria. The most common group of bacteria responsible for cutaneous wound infection are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Enterococcus* species.^{155,156} Cutaneous or sinus wounds are sometimes contaminated with saliva or other oral contaminants. In these cases, the microflora causing the infection may contain oral bacteria.

The prevalence of antibiotic-resistant strains has increased considerably in recent years. Methicillin-resistant *S. aureus* (MRSA) is proving to be the nemesis of modern surgery. Methicillin (meticillin) is a member of the penicillin class of antibiotic, and MRSA is resistant to this agent. However, MRSA is also resistant to a wide range of β -lactam and non- β -lactam antibiotics. As result, MRSA is often multi-drug-resistant, and once MRSA infection occurs, successful treatment may be very difficult to achieve. *Pseudomonas aeruginosa* is also an important pathogen as it is resistant to a wide range of antibiotics. Its involvement in infection is often indicated by the presence of a blue-green coloration of pus or exudate. This blue-green color is derived from pigments secreted by *P. aeruginosa*. MRSA and *P. aeruginosa* can colonize the skin and body of an individual without causing sickness and can cross-infect patients via hospital staff or contaminated medical equipment. Special attention must therefore be given to prevent the spread of this organism.

In the case of infected wounds associated with traumatic injury, exogenous organisms may enter into the wound with foreign bodies at the time of injury. The infection of simple traumatic wounds usually yields bacteria pre-existing at the site of injury. It should be remembered that spores of *Clostridium tetani* (the causative agent of tetanus) can enter the body through many kinds of wounds and although the topic is beyond the remit of this chapter it is important that clinicians understand the pathogenesis, clinical features, diagnosis, and prevention of tetanus.

Wound infections involving human bites commonly yield viridans streptococci, *Eikenella corrodens*, and oral anaerobes,^{157,158} whilst animal bites may involve unique microorganisms that reside within the mouth of the animal concerned. In bites inflicted by dogs and cats, *Pasturella* species are frequently involved.^{157,158}

Prevention of wound infection

Many risk factors influence the development of wound infections and awareness of these will help promote effective preventive strategies. Modern surgical techniques, medical care, and the use of prophylactic antibiotics will go some way to reduce this risk.

Risk of microbial contamination

The level of bacterial burden is the most significant risk factor. The US National Research Council group developed a system of classification for operative wounds based on the degree of microbial contamination.¹⁵⁹ A wound can be categorised as being clean, clean-contaminated, contaminated or dirty in terms of the risk of wound contamination and resultant infection. This classification is widely used to predict the likelihood of postoperative infection and to plan a

prophylactic antibiotic regimen. However, as the original version of this classification was made primarily for operative procedures in the respiratory, gastrointestinal, biliary, and genitourinary tracts, the definitions must be altered to fit the wound site involved.

Clean surgical wounds are defined as wounds with the lowest risk of infection and the smallest likelihood of contamination with endogenous bacteria (Table 29.32). Wounds in cutaneous tissue and paranasal sinus are sensitive to bacterial contamination. In wounds at these sites, saliva is the most common and clinically important contaminant. A clean wound is one where the surgical site can be prepared thoroughly, involves no significant tissue trauma or inflammation, and there is no communication with the oral cavity. The wound is closed by primary intention and, if necessary, drained with a closed drainage system. In contrast, although the oral microflora always contaminate oral wound sites, intraoral surgical wounds usually tolerate this contamination. This may be due to the host defense system and the excellent blood supply to the tissues. Therefore, inex-

tensive oral surgical wounds are generally managed in a similar manner to clean wounds, unless a patient's immunity is impaired or the wound exhibits significant tissue trauma or inflammation.¹⁶⁰

Clean-contaminated wounds are similar to clean wounds but infection is possible due to the likelihood of communication with the oral cavity under controlled conditions. The operative procedure usually commences in an uninfected environment and proceeds to incorporate entry into the oral cavity. Contaminated wounds result from operations where acute inflammation (without pus) is encountered or where there is a major breakdown in aseptic technique for fresh traumatic wounds. Dirty wounds occur when there is delayed treatment for a traumatic injury or the wound contains devitalized tissue or foreign bodies or involves an existing clinical infection.

Preventive strategies

The principle of preventive strategies for wound infection is to consider the presence or absence of any

Table 29.32 Classification of operative wounds and suggested strategies of prophylaxis for wound infection.

Classification	Criteria	Involved procedures and situation	Prophylactic antibiotic
Clean	Extraoral surgical wounds that are made under aseptic conditions and with no break in sterile technique, and have no evidence of infection, inflammation or contamination of the wound, and are primary closed	Tooth extraction and dentoalveolar surgery Submandibular and parotid gland surgery TMJ surgery	Unnecessary
	Unextensive oral wounds without significant inflammation or tissue devitalisation	Simple soft tissue surgery in oral or perioral regions	
Clean-contaminated	Same as clean but wound has the likelihood of communication with the oral cavity under controlled conditions (in the case of extraoral wound)	Major head and neck surgery Orthognathic surgery	Penicillin/cefazolin Penicillin
	Extensive operation within the mouth	Dental implants	Penicillin
	Intraoral wounds involving surgical placement of an implant	Surgery for simple fractures treated by transoral approach	Penicillin/cefazolin
	Graft surgery	Oroantral communication resulting from oral surgery	Penicillin
Contaminated	Operations where acute inflammation (without pus) is encountered or where there is major breakdown in aseptic technique or fresh traumatic wounds	Surgery for compound jaw fractures	Penicillin
		Fresh traumatic wound in the orofacial soft tissue*	Cefazolin
Dirty	Operations in which there is established clinical infection (with pus) or old traumatic wounds	Visibly contaminated or old orofacial traumatic wounds	Cefazolin
		Blunt trauma, gunshot wounds, bite wounds	Cefazolin
	Wounds containing significantly devitalized or infected tissues or foreign bodies	Surgery for suppurative osteomyelitis in the jaw	Penicillin

* Antibiotic prophylaxis is unnecessary where there are simple and fresh extraoral lacerations made with relatively clean objects.

factors that have an effect on the potential for wound infection and to manage them adequately before, during, and after surgery.

A healthy wound has a well maintained microbial homeostasis and therefore the first priority is to promote a healthy wound environment. Provision of a clean environment in the operative area is critical. Decontamination of the skin around the wound using soap, povidone-iodine, hexachlorophene solution or water is effective in reducing the risk of infection. Although surgeons may have concerns over bacteria residing in a patient's hair and advocate gentle shaving of the operative site, this action may increase the likelihood of wound infection as shaving induces minor trauma and may cause the breakdown of microbial homeostasis on the skin.^{160,161} Therefore, shaving should be kept to a minimum. It has been reported that the risk of infection increases with the length of time between shaving and surgery.¹⁶⁰ Therefore, if shaving is necessary, it should be performed as close to the time of surgery as possible. Tooth brushing, mechanical removal of dental plaque, and gingival scaling before surgery are, however, recommended.

Strict adherence to aseptic techniques and postoperative wound care are all necessary. Prolonged use of drains or long placement of sutures must be avoided, as they may become sources of postoperative contamination. Frequent irrigation of the wound with adequate use of antiseptics during the postoperative period reduces the likelihood of wound contamination.

Adequate surgical procedure, in accordance with the principles of surgery that optimize the wound-healing condition, is critical. Appropriate placement of the incision, rational flap design, meticulous hemostasis, elimination of dead spaces, and fastidious wound closure all help prevent wound infection. The prevention of tissue desiccation by constant irrigation is also effective. If the wound cannot be closed without tension or the persistence of pre-existing infection is suspected, then leaving the wound open should be considered. The wound edges may then come together naturally by means of granulation and contraction.

A traumatic wound within soft tissue should be treated as early as possible. In general, closure within 4 hours after injury is strongly recommended. Trapped foreign bodies, debris, clot, and necrotic tissue must be thoroughly removed through mechanical debridement and irrigation with copious amounts of saline solution. Open packing of a visibly contaminated wound with multiple foreign bodies that cannot be completely removed, may be effective in preventing infection.

Fractures should be treated soon after the injury has occurred. In particular, a compound fracture must be treated as soon as possible to minimize the size of the inoculum of bacteria contaminating the wound. Bony fragments must be fixed and immobilized adequately without any loose screws. Loose

teeth at the fracture site and teeth with a pre-existing abscess at the fracture site may be considered for removal to minimize the risk of postoperative infection.

It is important to correct pre-existing diseases that may depress the host defense system. Diabetes mellitus is perhaps the most common immunocompromising condition and therefore control of blood sugar is important. Diabetes also affects wound healing. Given the large number of undiagnosed cases of diabetes, blood glucose levels should be examined in all patients and controlled adequately before planned surgery. Careful monitoring and adequate control of blood glucose levels in the healing period in diabetic patients are also important to reduce the risk of wound infection. It has been suggested that the patient's blood glucose should be maintained below 200 mg/dl in the postoperative period.¹⁶²

Antibiotic prophylaxis

Antibiotic prophylaxis has had a positive impact on the incidence of infection after certain types of surgery. However, the clinician should not overestimate the effects of antibiotic prophylaxis and must recognize its limitations. Systemic prophylactic antibiotic should not be used routinely and should be tailored to the individual patient.

Benefit and risk of antibiotic prophylaxis

Antibiotic prophylaxis is highly effective in reducing the likelihood of infection. However, it has the potential risk of toxic and allergic reactions, drug interactions, alteration in the composition of normal host flora, and may promote an emergence of resistant bacteria. The cost of the antibiotic is also a matter that needs to be considered. In cases where the risk of infection is extremely low, an antibiotic provides little additional reduction in the incidence of infection. Such cases, therefore, do not need prophylactic antibiotic treatment.

Principles of antibiotic prophylaxis

The benefits versus the risk and the effectiveness versus cost should be considered for antibiotic prophylaxis. The most important factor to consider is the patient's host defense activity. In cases where the host immunity is significantly compromised or the surgical site may have reduced resistance to infection (e.g. a history of radiation therapy or poor blood supply), then antibiotic prophylaxis may be indicated.

Wounds categorized as clean-contaminated, contaminated, and dirty generally require antibiotic prophylaxis. As stated previously, oral wounds tend to have higher tolerance to microbial contamination and thus are more resistant to the establishment of infection. As such they are often treated as clean surgical wounds, in which antibiotic prophylaxis is unnecessary unless the patient has an immunocompromising

condition. However, if treated with a free flap, skin graft or implantation of foreign materials, prophylaxis should be used. Use of a prophylactic antibiotic is also advocated in surgery where there is an extensive operative area. The necessity of antibiotic prophylaxis for traumatic wounds within the oral cavity depends on the cause and mechanism of injury and the freshness and type of the wound.

Choice of antibiotic

The effectiveness of a prophylactic antibiotic is reliant on its efficacy against the predicted bacterial microorganisms most likely to cause infection, the extent of its tissue penetration, a lack of host toxicity, and its ability to cause a minimal disturbance to the intrinsic body microflora. An antibiotic with a narrow spectrum of activity should be chosen. Cost effectiveness should also be taken into consideration. In the case of oral wound, it is the penicillin class of antibiotic that fulfills these requirements. First-generation cephalosporin antibiotics may be adequate for the cutaneous or antral contamination.

Dose of antibiotic and duration of administration

The dosage of the prophylactic antibiotic should be the same or greater than that for therapeutic use. It should be remembered that the dose of the antibiotic is primarily determined by the serum level of the drug and the minimum inhibitory concentration (MIC) for the pathogen involved. If the surgical wound has a poor blood supply or the host defense mechanism is compromised, then a high dose of the antibiotic should be administered.

The timing of administration is critically important because the concentration of the antibiotic should be at its therapeutic level at the time of incision, during the surgical procedure, and, ideally, for a few hours postoperatively. An antibiotic administered preoperatively does exhibit a greater prophylactic effect than one administered postoperatively. Although many practitioners prescribe antibiotic postoperatively, it does not accomplish the true purpose of prophylactic antibiotic treatment. Oral antibiotics should be administered 30 minutes to 1 hour prior to the start of the operation. Intravenous or intramuscular antibiotics should be administered within 30 minutes of the incision time. Antibiotics should not be administered more than 2 hours prior to surgery. An additional dose of an intraoperative antibiotic should be administered to maintain an adequate serum concentration of the antibiotic during surgery if the operation is prolonged.

In the case of immunocompetent patients, if the surgery involves bacterial contamination that may occur only during the operation, antibiotic coverage during the operation may be sufficient and additional postoperative antibiotic may be unnecessary. In contrast, in circumstances where recontamination is suspected, use of an antibiotic postoperatively is rec-

ommended. Patients who have any factor that depresses the host defense mechanism or impedes wound healing have a great risk of recontamination during the healing period. In these cases, use of an antibiotic until evidence of biological wound sealing appears, is advocated.

Prophylaxis for wound infection on specific surgical procedure

There is contradiction over the effectiveness of prophylactic antibiotic use for each surgical procedure between published investigations. Although this section presents the guidelines for indication of antibiotic prophylaxis based on the latest pathologic and microbiologic knowledge and published clinical trials together with the authors' clinical experiences, actual use and regimen of antibiotic must be tailored to individual cases.

- *Endodontic procedures.* In pulpectomy, use of antibiotic prophylaxis is generally unnecessary regardless of the host's immunity level. However, antibiotic prophylaxis is advocated in cases of removal of infected necrotic material from the root canal of immunocompromised patients (e.g. treatment of asymptomatic (chronic) periapical lesions). In these situations the endodontic procedure itself can act as a trigger for acute infection.
- *Tooth extraction and other dentoalveolar surgery.* Most routine surgical procedures performed by dentists in healthy patients, such as tooth extraction, apicectomy, periodontal surgery, endodontic surgery, biopsy, do not require prophylactic antibiotics. Also, despite being a subject of controversy, third molar surgery (removal of impacted third molar in the mandible) does not require antibiotic prophylaxis. However, in cases of an immunocompromised host, prophylactic antibiotic treatment is recommended. The use of systemic antibiotics is also recommended where oroantral communication occurs. Use of antibiotics should be considered in cases of dental implant treatment. In situations where the maxillary sinus or the nasal cavity is exposed, prophylactic antibiotics should be used.
- *Removal of oral benign tumors and cysts in the jaw.* Indication of antibiotic prophylaxis follows the same principles as those of common dentoalveolar surgery. An extensive operation may require the use of prophylactic antibiotic.
- *Management of soft tissue trauma.* In cases of fresh wounds caused by simple traumatic injury within the mouth, antibiotic prophylaxis is unnecessary. Antibiotic prophylaxis is also unnecessary in simple and fresh extraoral lacerations made with relatively clean objects. However, in cases of blunt traumatic wounds, gunshot wounds, bite wounds caused by human or animal, lacerations from dirty

objects, traumatic injuries with delayed treatment, or contact with the saliva or any oral contaminants, use of antibiotic prophylaxis is recommended.

- *Management of fracture.* Fresh simple fractures of the condyle, ramus, and body of the mandible, with no saliva contamination, can be treated without antibiotic prophylaxis if treated through an extraoral approach.¹⁶⁰ However, if treatment is performed through intraoral incision, if treatment is delayed or if there is a pathologic fracture, use of antibiotic prophylaxis is recommended. Antibiotic prophylaxis is also advocated in cases of compound fracture of the mandible. Maxillary fractures involving the nasal cavity or paranasal sinuses similarly require antibiotic coverage.
- *Orthognathic surgery.* Orthognathic surgery performed via an extraoral approach is considered a clean procedure and antibiotic prophylaxis is unnecessary. However, if the surgery is undertaken transorally or if salivary or antral communication is anticipated, use of prophylactic antibiotics may be advocated.
- *Major maxillofacial surgeries.* Despite no scientific data, major surgical procedures in the mouth and face (e.g. sectioning and reconstruction of the jaw, plastic surgery using free flap, pedicle flap or biomaterials and bone or skin graft surgery) generally involve prophylactic antibiotic coverage.

Management of surgical site infections

Host defense systems serve to prevent microbial infection in cases where the tissue has received trauma through injury or surgery. The patient's own self-care as well as professional intervention through administration of antibiotic prophylaxis also minimize the likelihood of wound infection. Nevertheless, wound infection remains a clinical problem and might cause serious complications and sequelae.

Clinical findings of surgical site infections

The National Nosocomial Infections Surveillance System, which is the American national system for tracking health care-associated infections, has provided the diagnostic criteria of surgical site infections.¹⁶³ In summary, surgical site infections can be diagnosed if patients have at least one of the following conditions within 30 days of an operation or within 1 year of an important procedure: (1) purulent drainage becomes evident; (2) pathogenic organisms are isolated from the wound fluid or tissue; (3) at least one sign of inflammation (e.g. pain or tenderness, induration, erythema, local warmth of the wound) is present; (4) fasciae in the wounds spontaneously dehiscence; or (5) an abscess is formed. However, although these criteria are indeed helpful, diagnosis is often difficult because of the wide spectrum of possible clinical features and a variety of possible clinical

presentations. Most wound infections start with erythema and edema, which may be also seen as normal post-traumatic or postoperative inflammatory reactions. Therefore, it can be difficult to distinguish between pathogenic alternation and normal post-traumatic or postoperative inflammation.

In general, redness, pain, heat, and swelling associated with postoperative inflammatory reaction in the wound and periwound area decrease after the first few days, whilst such signs and symptoms related to surgical site infections tend to be persistent. The recurrence or further progression tends to manifest through increased erythema or swelling, thereby suggesting wound infection. High-grade, prolonged or recurrent fever can also be involved in wound infection, but postoperative fever is not a specific sign of wound infection and it is necessary to determine if the fever is actually due to infection. Invasive surgery itself can produce a low-grade fever for several days. Moreover, adverse effects of blood transfusion, side-effects of administered drugs, and other infections (e.g. acute viral nasopharyngitis, lung infection, urinary tract infection) can also induce fever.

The presence of purulent drainage and the formation of a fistula or abscess obviously indicate establishment of infection. The appearance of a purulent effluent or an increase in effluent volume may be indicative of wound infection. Therefore, the volume and nature of the drained effluent should be monitored carefully. Spontaneous dehiscence of fasciae is an indication of wound infection.

Infections of traumatic wounds that are not managed by surgical intervention are not considered as surgical site infections. However, the clinical features of these infections are generally similar to those of surgical site infections.

Diagnosis

Diagnosis is usually made with the consideration of all available factors, with special consideration given to the progress and course of local and systemic parameters. Imaging, in particular CT scans when available, can provide precise localization of any infection and source of contamination. However, these examinations are not necessarily helpful in all cases. Wide access and direct visualization through surgical reopening of the wound and drainage are in fact the most reliable means of investigation.

Laboratory data are sometimes helpful for diagnosis. However, it should be remembered that blood tests often reveal similar findings for acute infection in the postoperative period and for a few days after surgery if the wound is not infected. Moreover, the results may be affected by other underlying infections.

Management

Early intervention is important to prevent the progression of infection, with a subsequent onset of

associated complications and induction of sequelae. Management of wound infection will vary depending on the patient and commonly consists of cleansing the wound, application of surgical procedures, and antibiotic therapy.

An infected head and neck wound should be irrigated with copious amounts of physiologic saline solution. Dressing changes allow tissues to granulate, and the wound then generally heals by secondary intention over several weeks. Early closure of infected wounds is often associated with a relapse of infection and wound dehiscence. Opening the wound is recommended to ensure complete drainage, to promote exploration of all contiguous sites contacting the infection, and to allow an assessment of the potential sources of contamination. Surgical closure of fistulas and procedures to stop salivary contamination in the extraoral wound are both necessary. Rejection of the infected implanted material is the body's natural response and this does require removal. Antibiotic therapy is rarely sufficient on its own to salvage a contaminated implant.

In mild cases with no apparent wound necrosis or fistulae, management can be achieved with antibiotic therapy alone, avoiding the need for surgical intervention. However, a postponement or unnecessary delay in performing surgery must be avoided if intervention is required.

With regard to choice of antibiotics, penicillin, clindamycin, and metronidazole are all adequate candidates for empiric selection for those infections involving only oral contamination. For infections involving mixed contamination of oral and cutaneous organisms, use of broad-spectrum antibiotics, such as co-amoxiclav, β -lactam agents with sulbactam, cephalosporins, imipenem, and fluoroquinolones, is advocated. As mentioned so far, wound infection involves various types of organisms. Moreover, the wound infection often includes organisms that are resistant to antibiotics often used in the prophylaxis regimen. Culture and sensitivity testing should be performed in all cases and antibiotic selection should be reassessed based on results. A specimen from an infected

wound is usually contaminated with bacteria from the normal commensal microflora even if the specimen is obtained by careful aspiration. Careful interpretation of microbiologic data is therefore required, although it is often problematic to distinguish causative pathogens from those uninvolved organisms that colonize the wound.

Postextraction infection and alveolar osteitis (dry socket)

Postextraction infection is a form of surgical site infection that is perhaps the most commonly encountered by dentists. It is, however, distinct from alveolar osteitis which may exhibit a similar clinical picture.

Postextraction infection

Clinical signs and symptoms of postextraction infection usually appear 2–4 days after surgery. A pre-existing infection, inadequate oral hygiene in the healing period, peeled calculus or restoration material trapped in the operative site, and root or bone fragments left in the socket, all predispose to the infection. Immunocompromising conditions are also involved in predisposition. The microbiology of the infection is similar to that of other odontogenic infections. The disease often takes an acute form, and spontaneous pain, erythema, and elevated temperature of the wound may result. These symptoms are somewhat similar to alveolar osteitis, but, in contrast, postextraction infection presents with suppuration and apparent swelling. In the case of the mandibular molar, trismus can occur. Infection may spread extensively to involve adjacent soft tissues and jaw, and might cause fascial space infections, osteomyelitis, and maxillary sinusitis.

Fig. 29.95 Intraoral views and radiographs of cases of postextraction infection and squamous cell carcinoma (SCC). (a) Spontaneous drainage of pus from the extraction socket is evident in patients with postextraction infection. (b) (i) The SCC patient had no particular signs or symptoms except delayed healing of an extraction socket. (ii) Radiographic imaging of the SCC patient shows relatively wide destruction of bone around extraction socket.

Some cases primarily have a chronic form, without an apparent acute stage episode. In these cases, subjective symptoms are minimal, but patients often complain of delayed wound healing with or without pus discharge. The socket is usually filled with inflammatory granulation, and sometimes contains foreign materials, including necrotic bone fragments and broken tooth pieces.

Diagnosis is made based on the patient's history, clinical signs, and symptoms, laboratory tests, and imaging analysis. It should be noted that malignant tumors in the gingiva, jaw, and maxillary sinus can have a similar clinical presentation. These tumors produce a granulation-like mass in the socket after extraction of tooth (Fig. 29.95). Although differentiation from carcinoma is often difficult, careful radiographical study is often helpful. In the case of oral carcinoma, a range of irregularities of alveolar bone absorption in the tooth socket might be seen due to tumor invasion of the bone.

Treatment of the acute phase includes antibiotic therapy and drainage by incision. After the acute phase has subsided, debridement or curettage to remove necrotic tissues, inflammatory granulations, and foreign bodies from the socket may be necessary to prevent recurrence. As stated previously, the clinician must keep in mind the possible involvement of a malignant tumor. If the lesion is malignant, an invasive procedure may promote additional growth of the tumor and increase the risk of metastasis. If the possible involvement of a malignant tumor cannot be ascertained, a biopsy should be performed prior to surgical treatment.

Alveolar osteitis

Alveolar osteitis refers to the inflammation of alveolar bone following extraction of the tooth. It occurs when the blood clot at the site of the tooth extraction is dislodged, exposing underlying bone and nerves and thus causing increasing pain (Fig. 29.96). This condition has also been referred to as a dry socket and is not a suppurative infection. Alveolar osteitis is a major complication of tooth extraction, even when the extraction has been performed expertly and in an

Fig. 29.96 Alveolar osteitis. Exposed bone is seen.

aseptic manner. It occurs in 1–4% of all routine tooth extractions, and is more common following mandibular third molar extraction.^{164,165} Incidence rates of between 5 and 10% have been reported after removal of impacted mandibular third molars.^{166,167}

Although the etiology of alveolar osteitis has not fully been clarified, it is thought to involve a complex interaction between excessive localized trauma, bacterial invasion and their association to plasmin and the fibrinolytic systems.¹⁶⁷ Suggested risk factors include previous experience of alveolar osteitis, technical difficulties of surgery, poor oral hygiene of patient, active or recent history of acute ulcerative gingivitis or pericoronitis associated with the tooth to be extracted, smoking, use of oral contraceptives, and immunocompromised individuals.¹⁶⁷ It has been reported that less experienced surgeons may more often cause alveolar osteitis than more experienced surgeons and this has been related to the likely extent of traumatic tissue damage to the socket.

Symptoms generally start on the first to third day after extraction of the tooth. The exact duration of the condition varies and is dependent on the severity of the disease, but it usually ranges from 5–14 days. The denuded alveolar bone may be painful and tender. The pain is usually described as a throbbing ache or intense continuous pain irradiating from the empty socket to the ipsilateral ear and temporal region. The socket is very sensitive to chemical and thermal irrigation due to the exposure of nerve endings in the alveolar bone. Alveolar osteitis may also be accompanied by malodor and/or taste, and suppuration is generally absent. Regional lymphadenopathy is occasionally seen, but fever is uncommon.

It is necessary to exclude any other cause of pain on the same side of the face, especially simple postextraction pain and infection. Alveolar osteitis usually does not occur before the first postoperative day and the pain commonly appears suddenly or increases 1–3 days following extraction of the tooth. In contrast, in normal postextraction pain, the peak of pain intensity is usually on the operative day and this decreases with time. Postoperative infection usually induces a degree of swelling and often shows pus discharge.

Although alveolar osteitis is a condition in which there is loss of the blood clot from the socket, the socket may not always be completely empty. It may still contain a partially necrotic blood clot, often seen as a gray or dark yellow material. Diagnosis is confirmed by gently passing a small probe into the extraction wound. During probing, bare bone is encountered, which is extremely sensitive.

Alveolar osteitis is a self-limiting condition and therefore it generally resolves spontaneously. As there is no real treatment for alveolar osteitis itself, management of alveolar osteitis is directed primarily toward the relief of pain. Treatment options include gentle irrigation of the socket with a warm sterile isotonic saline solution, and packing with a zinc oxide–eugenol paste on iodoform gauze for relief of acute

pain. Coverage of the socket using a periodontal pack may be effective in preventing additional irritation of the socket. NSAIDs should be administered systemically for pain relief. The agent should be chosen based on the severity of pain, but use of potent types of NSAIDs is often required. Curettage should not be employed because it may destroy any previous attempt at normal healing and increase pain. The routine use of systemic antibiotics is not recommended, because alveolar osteitis is not a true infection. Use of topical antibiotics is also of little therapeutic value. However, if the patient is immunocompromised, use of a systemic antibiotic such as metronidazole may be advocated.

Prevention of hematogenously spreading infections

Hematogenous spread of bacteria from the wound site to a distal location can be of clinical concern. Oral bacteria can cause infections at locations physically separate from the portal of entry of the bacteria. These infections result from hematogenous spread of bacteria and bacteremia plays a significant role.

Although blood is normally sterile, bacteria in the local infection site or commensal bacteria within the body may enter into the bloodstream. The condition of bacteria being present in the blood is called bacteremia (see the earlier section, Complications of maxillofacial infections). Although the immune response to the bacteria could lead to sepsis and septic shock, bacteremia is usually harmless and transient, because of the actions of a vigorous immune system response. Body sites that harbor high numbers of microorganisms are likely sources of bacteremia. Although suppurative infection sites and the mucosa of the gastrointestinal tract are included in such instances, the mouth is the most important source of bacteremia. Normal daily activities, such as the use of mouth wash, tooth brushing, and chewing, all induce bacteremia.^{168–170} In addition, surgical procedures in the mouth or dental procedures inducing bleeding cause bacteremia, and occurrence of bacteremia following tooth extraction is virtually 100%.^{171–173} During bacteremia, bacteria do spread via the bloodstream throughout the body. Although these organisms are usually completely eliminated by the body's reticulo-endothelial system, on rare occasions, bacteria can survive and settle in certain parts of the body and cause infections away from the original site. Infective endocarditis (IE) and total joint replacement (TJR) infection are representatives of infections involving hematogenous dissemination of bacteria.

This section discusses the prevention of these infections based on the latest guidelines provided by authoritative medical organizations, namely the American Heart Association (AHA), the National Institute for Health and Clinical Excellence (NICE, UK) the British Society for Antimicrobial Chemo-

therapy (BSAC), the American Academy of Orthopedic Surgeons (AAOS), and the American Dental Association.

Infective endocarditis

IE is an inflammation of the inner layer of the heart (the endocardium), caused by microorganisms. The most common structures involved are the heart valves, especially if previously damaged congenitally, from surgery, by autoimmune mechanisms or simply as a consequence of old age. Bacteremia is a necessary event in the development of IE and delivers microorganisms to the surface of the valve. Although bacteremia would normally be cleared quickly with no adverse consequences in a healthy individual, a deformed heart value with its altered endothelial surface can be susceptible to bacterial adherence and subsequent multiplication. Therefore, if heart valves have been damaged, or replaced with an artificial biomaterial, bacteria have a greater chance of colonization.

In the case of IE, bacteria multiply and small clumps of material called vegetations may develop on the infected valves. These vegetations contain microorganisms, small blood clots, and other debris from the infection. The vegetations may prevent function of affected valves and allow infection to spread to other areas of the endocardium or heart tissue. Fragments of the vegetations (emboli) can detach and travel in the bloodstream to other parts of the body and cause distal infections with additional signs and symptoms. Usual initial signs of IE are intermittent fever, and subsequently heart murmurs, which result from abnormal flow of blood through faulty or damaged valves. Complications may appear if the infection is left untreated or if treatment is delayed. Damage to heart valves may lead to serious heart problems, including heart failure and heart abscess. Moreover, emboli may cause vascular obstruction (embolism) and block blood flow in other parts of the body. This can result in stroke, kidney failure, heart attack, and damage to gastrointestinal organs. Splinter hemorrhages, Janeway lesions (painless hemorrhagic cutaneous lesions on the palms and soles), Osler's nodes (painful subcutaneous lesions in the distal fingers), and Roth's spots (oval retinal hemorrhages) are all related to embolisms.

A variety of causative organisms are associated with IE, with staphylococci, viridans streptococci, and enterococci being the most common pathogens involved.¹⁷⁴ Despite improved prognosis due to advances in treatment, IE remains a life-threatening disease.

As described previously, bacteremia is an important factor in the development of IE. Surgical procedures that may cause bacteremia, and in particular invasive surgical procedures within the mouth, are therefore thought to be associated with development of IE in patients with predisposing factors. Prevention

of IE associated with surgical procedures has been the subject of much research, and several international medical societies and organizations, especially the AHA, have provided guidelines for prevention based on research findings.

In the AHA guidelines released in 1997, cardiac conditions are divided into high-, moderate-, and negligible-risk categories based on potential outcome if IE develops; the use of antibiotic prophylaxis is recommended when performing certain surgical and dental procedures in patients with high or moderate risk.¹⁷⁵ However, these guidelines were not evidence

Table 29.33 Indications of antibiotic prophylaxis against infective endocarditis (AHA).¹⁷⁶

Cardiac conditions where prophylaxis is recommended

Prosthetic cardiac valve

Previous infective endocarditis

Congenital heart disease (CHD):*

Unrepaired cyanotic CHD, including palliative shunts and conduits

Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure

Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

Dental procedures requiring antibiotic prophylaxis

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa in patients with the cardiac conditions outlined above

* Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

based. There has been no reliable clinical trial to assess the effect of antibiotic regimens in the prevention of IE. It has been noted that “appropriate” antibiotic prophylaxis does not prevent IE in all patients, and the risk of fatal anaphylaxis caused by administration of antibiotic may be greater than the effect of the antibiotic on prevention of IE. In addition to these criticisms, IE causation has recently shifted from procedure-related bacteremia to cumulative bacteremia involving daily activities such as chewing or tooth brushing. The AHA radically revised their guidelines in 2007.¹⁷⁶ The new guidelines emphasize good oral hygiene for preventing IE, and restrict the indication for antibiotic prophylaxis. Although all dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa remain as factors for prophylaxis indication, the indication for antibiotic prophylaxis should be restricted only to patients with the highest-risk cardiac conditions. These include a history of previous endocarditis, cardiac valve replacement surgery or a surgically constructed systemic or pulmonary shunt or conduit (Table 29.33). With regard to a regimen of antibiotic prophylaxis, administration of a single oral or intravenous dose of antibiotic is recommended. Oral administration of amoxicillin 1 hour prior to a dental procedure is recommended as a first-choice antibiotic, although first- or second-generation oral cephalosporin, clindamycin, azithromycin, and clarithromycin are alternatives. In patients who are unable to take oral medication, intramuscular or intravenous administration of ampicillin, cefazolin, ceftriaxone or clindamycin is recommended (Table 29.34).

NICE is an independent organization that provides national guidance on promotion of good health and prevention and treatment of ill health to the National Health Service in the UK. NICE has recently recom-

Table 29.34 AHA regimens for antibiotic prophylaxis of infective endocarditis.¹⁷⁶

Situation	Agent	Regimen: single dose 30–60 minutes before procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g, IM/IV	50 mg/kg, IM/IV
	or Cefazolin or ceftriaxone	1 g, IM/IV	50 mg/kg, IM/IV
Allergic to penicillins or ampicillin	Cephalexin*	2 g	50 mg/kg
	or Clindamycin	600 mg	20 mg/kg
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone	1 g, IM/IV	50 mg/kg, IM/IV
	or Clindamycin	600 mg, IM/IV	20 mg/kg, IM/IV

IM/IV, Administration by intramuscular or intravenous route.

Cephalosporins should not be used in a person with a history of anaphylaxis, angioedema or urticaria with penicillins or ampicillin.

* Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.

mended that antibiotic prophylaxis should not be given to people at risk of IE undergoing dental procedures including tooth extraction.¹⁷⁷ This guidance is more restrictive compared with the AHA guide to clinical use of antibiotics in preventing IE. Although there remains debate over the strategy of antibiotic prophylaxis for patients with the highest-risk cardiac conditions, most authorities, including the AHA, agree that there are limited effects of antibiotic prophylaxis in prevention of IE. The non-use of antibiotic prophylaxis during invasive procedures in the mouths of patients with the highest-risk cardiac conditions would be advocated unless reliable evidence to support the effect of antibiotic prophylaxis is present.

Table 29.35 Indications of antibiotic prophylaxis for hematogenous total joint replacement infection (AAOS, 2003).¹⁷⁸

Conditions placing patients at risk for prosthetic joint infection
Prosthetic joint placed within 2 years
Rheumatoid arthritis
Systemic lupus erythematosus
Drug- or radiation-induced immunosuppression
Previous prosthetic joint infections
Malnourishment
Hemophilia
HIV infection
Insulin-dependent (type 1) diabetes
Malignancy
Dental procedures requiring antibiotic prophylaxis for patients with condition outlined above
Tooth extractions
Periodontal procedures including surgery, subgingival placement of antibiotic fibers/strips, scaling and root planing, probing, recall maintenance
Dental implant placement and replantation of avulsed teeth
Endodontic instrumentation or surgery only beyond the apex
Initial placement of orthodontic bands but not brackets
Intraligamentary and intraosseous local anesthetic injections
Prophylactic cleaning of teeth or implants where bleeding is anticipated

Infection of total joint replacement

TJR is a surgical procedure in which certain parts of an arthritic or damaged joint, such as a hip, knee or shoulder, are removed and replaced with a prosthesis. TJR is generally indicated only for those patients who have severe arthritic conditions. Infections of a TJR can result in failure of the replacement and the need for extensive revision and treatment. Infections usually result from hematogenous seeding of bacteria on to joint implants from a variety of sources, both in the early postoperative period and for many years following implantation. There has been great concern over the involvement of oral bacteria, which can disseminate from the oral cavity in the blood after normal daily activities such as toothbrushing and chewing, and after invasive dental treatment such as tooth extraction.

The analogy of prosthetic joint infections with IE is invalid as the anatomy, blood supply, microorganisms, and mechanisms of infection are all different. Therefore, in contrast with IE, antibiotic prophylaxis for TJR infection remains supported. AAOS recommends antibiotic prophylaxis for all TJR patients who have had previous prosthetic joint infections, and for those with other conditions that may predispose the patient to infection (Table 29.35) prior to any invasive procedure that may cause bacteremia. Dental extractions, periodontal procedures (including surgery, scaling and root planing, probing, recall maintenance), dental implant placement, replantation of avulsed teeth, endodontic treatment, and intraligamentary and intraosseous local anaesthetic injections are included as invasive procedures for which antibiotic prophylaxis is indicated. In contrast, antibiotic prophylaxis is not advocated for patients with pins, plates and screws or other orthopedic devices that are not within a synovial joint or at increased risk for hematogenous seeding by microorganisms. The recommended antibiotic regimen is presented in Table 29.36.

In 2009, the AAOS released new information for antibiotic prophylaxis which included changes with regard to patients who have undergone TJR surgery. It is now advised that the length of time after the surgery is not an influencing factor and as such therefore

Table 29.36 Suggested antibiotic prophylaxis regimens against hematogenous total joint replacement infection.¹⁷⁸ No second doses are recommended for any of these dosing regimens.

Patient type	Suggested drug	Regimen
Patients not allergic to penicillin	Cephalexin, cephadrine or amoxicillin	2 g orally 1 hour prior to dental procedure
Patients not allergic to penicillin and unable to take oral medications	Cefazolin or ampicillin	Cefazolin 1 g or ampicillin 2 g intramuscularly or intravenously 1 hour prior to the dental procedure
Patients allergic to penicillin	Clindamycin	600 mg orally 1 hour prior to the dental procedure
Patients allergic to penicillin and unable to take oral medications	Clindamycin	600 mg intravenously 1 hour prior to the dental procedure

prophylactic antibiotic should be given to all patients receiving dental treatment who have previously undergone TJR surgery. However, it is generally accepted that there is little evidence to support the effectiveness of antibiotic prophylaxis on the prevention of infection. Concern has been expressed that the 2009 revision will result in an increased use of prophylactic antibiotic therapy and some of this increase may be unnecessary. Prophylactic antibiotic usage in accordance with the recent statement has been accepted in some countries but not others, including the UK. BSAC has advised that antibiotic therapy is not required for dental treatment of patients with TJR. BSAC consider that it is unacceptable to expose patients to potential adverse effects of antibiotic therapy when there is no evidence that it has any benefit. Differences in opinion will continue to exist and it is likely that further changes in the recommendations for the use of prophylactic antibiotic therapy in relation to dental treatment in patients with TJR will be proposed in the future.

Established odontogenic infections are highly likely to induce a bacteremia of sufficient magnitude to cause a prosthetic joint infection. Therefore, these infections should be eliminated prior to implementation of a TJR.

Oral fungal infections

A variety of fungal species have been recovered from the oral cavity of humans including *Saccharomyces* spp., *Geotrichum* spp., and *Cryptococcus* spp. However, by far the most prevalent fungal isolate are those species belonging to the genus *Candida*.

Candida infections

It is the infections caused by *Candida* (candidoses or candidiasis) which are the most frequent forms of oral fungal infection encountered. Oral candidosis primarily occurs in debilitated hosts, with perhaps the best example of this being the high incidence of

oral candidosis in human immunodeficiency virus (HIV)-positive individuals and acquired immunodeficiency syndrome (AIDS) sufferers.

Etiology and pathogenesis

Candida species are actually regarded as being members of the normal oral microflora and their involvement in infection in the debilitated host leads to their description of being opportunistic pathogens.⁹ The rate of commensal carriage of *Candida* varies in the literature and depends on the demographics of the studied population group. Carriage rates ranging from 20% to 80% have been reported. Although approximately 10–12 *Candida* species have been associated with human infections, over 80% of infections are caused by *Candida albicans*.

The transition from healthy oral carriage to the diseased state can occur due to a variety of reasons including both physiologic and iatrogenic host factors (Table 29.37).

Clinical features

Oral candidosis is not a single infection, and indeed four distinct primary forms of oral candidosis have been described, based on clinical presentation.

Pseudomembranous candidosis

Pseudomembranous candidosis (Fig. 29.97) manifests as the occurrence of white plaque-like lesions on the oral mucosa. The infection is synonymous with the description “oral thrush” and in the past has been most frequently seen in the mouths of neonates and elderly individuals. The infection can present on any oral mucosal surface but is most likely to be seen on the surface of the labial and buccal mucosa, hard and soft palate, and tongue. One of the key distinguishing features of pseudomembranous candidosis is the ability to remove the pseudomembranes by gentle scraping, thus revealing an erythematous underlying mucosa. Microscopic examination of the pseudomembranes reveals the presence of desquamated epithelial cells together with fungal elements that can be seen by either traditional Gram staining or the use of

Table 29.37 Host-related factors associated with oral candidosis.

Local host factors
Denture wearing
Steroid inhaler use
Reduced salivary flow
Carbohydrate-rich diet
Systemic host factors
Extremes of age
Endocrine disorders, e.g. diabetes
Immunosuppression
Receipt of broad-spectrum antibiotics
Nutritional deficiencies

other staining techniques including the Periodic Acid Schiff stain or Gomori's methenamine silver staining.

Pseudomembranous candidosis has historically been considered to be an acute infection and correction of any identified host-related factor generally results in resolution of the condition. However, the advent of HIV infection in recent years and the associated increase in AIDS has resulted in a more chronic variant of pseudomembranous candidosis. In immunocompromised individuals, progression of oral infection to esophageal involvement can arise, leading to complications such as difficulties in swallowing and chest pain. Steroid inhaler use, particularly in young adults as part of the management of asthma, is associated with frequent cases of pseudomembranous candidosis in the soft palate.

Acute erythematous candidosis

Acute erythematous candidosis (Fig. 29.98) is seen as painful reddened patches on the oral mucosa and most frequently on the dorsum of the tongue. The administration of broad-spectrum antibiotics is associated with the occurrence of this form of oral candidosis, which is believed to occur as a result of the subsequent reduction of the bacterial community within the oral microflora. This in turn allows the numbers of *Candida* to increase due to reduced competition in the oral environment. Once antibiotic treatment has stopped, the lesions tend to resolve naturally without therapeutic intervention. It is the relationship between antibiotic therapy and acute erythematous candidosis that has given rise to its alternative description, namely, antibiotic sore mouth.

Chronic erythematous candidosis

The most prevalent form of oral candidosis is chronic erythematous or "*Candida*-associated denture stomatitis" (Fig. 29.99). The infection presents as a reddened mucosa beneath the fitting surface of a denture and up to 65% of denture wearers show clinical signs of this infection.¹⁷⁹ The condition is often asymptomatic and will develop under any acrylic denture or intra-oral appliance. It is, however, almost invariably seen in the palate rather than on the mandibular mucosa.

Fig. 29.98 Acute erythematous candidosis of the tongue.

Fig. 29.99 Chronic erythematous candidosis of the palate.

A key factor in the occurrence of this infection is poor oral hygiene or the presence of an ill-fitting denture.

Chronic hyperplastic candidosis

Chronic hyperplastic candidosis (CHC) (Fig. 29.100) is a less common form of oral candidosis and its occurrence is highest amongst middle-aged men who are tobacco smokers. CHC tends to be an asymptomatic infection, although some untreated cases (5–15%) may become dysplastic.¹⁸⁰

CHC is characterized by hyphal invasion of the oral epithelium by *C. albicans* and these can be seen following histological staining of biopsy material. It is the presence of the hyphae, together with an inflammatory cell infiltrate, which are the diagnostic features of this condition. As a consequence a biopsy is an essential component of the diagnostic procedure for CHC.

Whilst CHC can occur at any site on the oral mucosa it is most frequently encountered bilaterally as white patches in the buccal commissure regions. CHC lesions cannot be removed by gentle scraping without bleeding, thus distinguishing it from pseudomembranous candidosis. Two lesional types are described based on clinical appearance: (1) homogeneous lesions which are smooth and white; and (2) heterogeneous lesions appearing with a nodular or speckled appearance. It has been proposed that the heterogeneous form is more likely to undergo malignant transition.¹⁸¹

Fig. 29.100 Chronic hyperplastic candidosis in the commissure region of the mouth.

Fig. 29.101 Angular cheilitis.

Secondary forms of oral candidosis

In addition to the above described primary forms of oral candidosis, *Candida* are associated with other oral lesions, including those of angular cheilitis, median rhomboid glossitis, and chronic mucocutaneous candidosis.

Angular cheilitis

Angular cheilitis (Fig. 29.101) is seen as erythematous lesions at the angles of the mouth and is often associated with the occurrence of other forms of oral candidosis, most notably chronic erythematous candidosis. The exact role of *Candida* in the development of the lesion is unclear since microbial culture often reveals co-isolation with the bacterial species *Staphylococcus aureus*.

Median rhomboid glossitis

Median rhomboid glossitis (Fig. 29.102) presents as a symmetrically shaped area in the midline of the dorsum of the tongue. This chronic condition is strongly

Fig. 29.102 Median rhomboid glossitis.

Fig. 29.103 Chronic mucocutaneous candidosis.

associated with both smoking and the use of inhaled steroids. Isolation of *Candida* from the lesions is very common.

Chronic mucocutaneous candidosis

Chronic mucocutaneous candidosis (CMC) (Fig. 29.103) describes a collection of candidal infections largely confined to the skin, mucous membranes, and nails. A key predisposing factor would appear to be impaired cellular immunity against *Candida* and CMC is generally associated with an underlying congenital condition.

Diagnosis

Diagnosis of oral candidosis is dependent on the infection type and, whilst clinical appearance is extremely important, culture of *Candida* directly from the lesion is often used. Oral samples are generally cultured on Sabouraud dextrose agar which supports the growth of all oral *Candida* species with the added benefit of suppressing bacterial growth due to its relatively low pH.¹⁸² Occasionally microbiologists will incorporate antibiotics into the agar to further increase its selectivity. In recent years, other media, e.g. CHROMagar® *Candida*, have been developed that differentiate *Candida* species based on colony color (Fig. 29.104). The advantage of such media is that the presence of multiple *Candida* species in an infection can be determined which has importance in subsequent therapeutic selection. Identification of yeasts is confirmed through supplemental tests based on morphologic and physiologic characteristics.

Management

In the correct management of oral candidosis, it is firstly imperative that identification and control of any underlying and predisposing host factor is established. In addition, a range of antifungal agents is available to directly target the infecting *Candida*. The polyene antifungals, amphotericin B and nystatin are

Fig. 29.104 Various types of yeast colonies grown on CHROMagar® *Candida*. *Candida albicans*, which is the primary pathogen of oral fungal infections, yields green colonies on the agar, whilst the large majority of non-*albicans* *Candida* species produce purple colonies.

generally regarded to have the broadest spectrum of antifungal activity and are frequently used topically in a variety of oral formulations, including suspensions, lozenges, and pastilles. Polyenes are poorly absorbed through the gut and as such their use is relatively limited.

Azole antifungals have a fungistatic rather than fungicidal activity against *Candida* species¹⁸³ and consequently it is important to correct underlying host conditions during therapy to promote infection resolution. The azole antifungals are divided into two classes, imidazoles and triazoles, by chemical property. The two triazole agents frequently used to treat oral candidosis are fluconazole and itraconazole. The major benefit of these drugs is that they can be given orally and are well absorbed from the gut. Miconazole is a representative of imidazole agents, which is only used topically. It interacts with warfarin even when applied topically and should therefore be avoided in patients on coumarin anticoagulants.

Other fungal infections

Whilst *Candida* colonization of the oral cavity and associated infection are relatively frequently encountered, other oral fungal infections are rare and often restricted to infection in seriously immunocompromised patients. Often, oral infection occurs following spread of the causative organisms to the oral cavity from an already existing infection elsewhere in the body, often the lungs. The reverse is also true, with risk of dissemination of oral infection to cause subsequent systemic infection. Whilst much less common than candidosis, infections by these other fungal species are often more serious, with not just superficial injury to the oral mucosa occurring, but also infection to the paranasal sinuses, the orbit, and cranial base. Examples of these infections include mucormycosis, paracoccidiomycosis, and aspergillosis.

Mucormycosis

Mucor and *Rhizopus* species are those most responsible for mucormycosis. The infection is extremely rare in healthy individuals and is most often encountered in patients in African or Latin American countries. Conditions most commonly associated with mucormycosis include organ transplantation, leukemia/lymphoma treatment, and AIDS. The causative fungi are normal environmental organisms, often associated with decaying vegetation. During human infection these fungi can be isolated from the nose and mouth. Symptoms of this infection include fever, an acute sinusitis with erythema on the overlying skin, and orbital edema. Treatment of mucormycosis must involve surgical removal of all infected tissues which may include the palate, and nasal or eye structures. Amphotericin B may be used in treating this aggressive infection but its value in combating the disease remains uncertain.

Paracoccidiomycosis

The organism responsible for paracoccidiomycosis is *Paracoccidioides brasiliensis*. This species is a dimorphic environmental fungus that infects immunocompromised individuals through inhalation of conidia. At 37°C, yeast is the predominant growth form (as opposed to a mould at temperature <25°C) and these yeasts are responsible for the observed ulcerative lesions that manifest within the mouth, nose, larynx, and oropharynx. As with *Candida* species, Sabouraud dextrose agar will permit isolation of *P. brasiliensis* and histologic analysis of infected tissue will reveal characteristic granulomatous inflammation with infecting yeast. Amphotericin B in combination with sulfa drugs and itraconazole is the preferred treatment regimen for this infection; with early treatment the prognosis for recovery is usually good.

Aspergillosis

The term *Aspergillosis* is a collective one for infections caused by fungi of the genus *Aspergillus*. Around 20 species have been associated with human infection with *A. flavus*, *A. fumigatus*, *A. nidulans*, and *A. niger* being frequently implicated. As with the fungi mentioned previously, *Aspergillus* species are primarily associated with the environment, and soil and vegetation in particular.⁹ Infection of debilitated individuals generally occurs following inhalation of conidia.

Oral invasive aspergillosis is a very rare condition. Early recognition through biopsy and microbiologic analysis of the lesions, followed by immediate antifungal therapy is essential to prevent extensive tissue damage. Aspergillosis of the oral region is believed to start on the marginal gingiva and then spread to the adjacent tissues, including the mucosa, muscle, and alveolar bone. Treatment of oral invasive aspergillosis involves both surgical and medical intervention with aggressive systemic antifungal therapy accompanying the debridement of all necrotic tissue required after diagnosis to ensure successful treatment.

Oral and perioral viral infections

A variety of viral infections have been encountered in the mouth and perioral tissues. However, by far the most prevalent are those caused by members of the DNA herpes group of viruses (Table 29.38). It has been estimated that 90% of adults are chronic carriers of at least one type of herpes virus, which are acquired as a result of infection during childhood or early adulthood. Following initial (primary) infection, these viruses have the property of latency and reside in the tissues asymptotically for the remainder of the patient's life. Under certain conditions latent virus will reactivate to cause recurrent symptoms (secondary infection). It is also recognized that herpes viruses are periodically shed without causing symptoms in the saliva of up to 70% of the population at least once

Table 29.38 Orofacial conditions associated with the human herpes group of viruses.

Virus	Trivial name and acronym	Clinical condition
Human herpes virus 1	Herpes simplex virus 1 (HSV-1)	Primary herpetic gingivostomatitis Herpes labialis Recurrent herpetic ulceration
Human herpes virus 2	Herpes simplex virus 2 (HSV-2)	Genital herpes (Rarely: Primary herpetic gingivostomatitis Herpes labialis Recurrent herpetic ulceration)
Human herpes virus 3	Varicella zoster virus (VZV)	Chickenpox Herpes zoster (shingles) Ramsay Hunt syndrome
Human herpes virus 4	Epstein Barr virus (EBV)	Infectious mononucleosis (glandular fever) Nasopharyngeal carcinoma Burkitt's lymphoma Hairy leukoplakia
Human herpes virus 5	Human cytomegalovirus (HCMV)	(Possibly oral ulceration or salivary gland swelling in immunocompromised patients)
Human herpes virus 6	Human herpes virus 6 (HHV-6)	Roseola infantum (Nagayama's spots)
Human herpes virus 7	HHV-7	None known
Human herpes virus 8	Human herpes virus (HHV-8)	Kaposi's sarcoma

a month. Such shedding represents a risk of spread of the virus and in part explains the widespread nature of herpes simplex type 1 (HSV-1) in the community. Reactivation of HSV-1 has been implicated as an etiological factor in periodontal disease and erythema multiforme.^{184,185} Other viruses that may manifest in the mouth include cosackieviruses, paramyxoviruses, and papilloma viruses.

Primary herpetic gingivostomatitis

This condition is almost uniformly caused by primary infection with HSV-1 although rare cases involving herpes simplex type 2 (HSV-2), the herpes virus associated with genital tissues, have been reported.⁹ Infection classically occurs during the first few years of life and the symptoms of mild oral discomfort over 4–5 days may be misdiagnosed as an episode of teething. In older children or early adulthood, the presentation is often more dramatic and characterized by the development of blood-crusted lips (Fig. 29.105),

Fig. 29.105 Primary herpetic gingivostomatitis presenting as widespread oral vesicles and erosions.

Fig. 29.106 Multiple ulcers due to primary herpetic gingivostomatitis.

gingival swelling, multiple oral ulcers (Fig. 29.106), lymphadenopathy, and pyrexia. The mucosal lesions develop as intraepithelial vesicles but these soon rupture to produce the typical shallow yellow ulcers with surrounding erythema. All signs and symptoms of primary infection resolve within 10 days.

Diagnosis can often be made on the nature of the clinical presentation alone. However, it can be confirmed by isolation of the virus in tissue culture. Since high numbers of virus will be present not only on the ulcerated mucosa but also within the saliva it is not necessary to identify specific lesion and a swab from any oral site will be sufficient. The swab should be placed in viral transport medium for transfer to the laboratory. Results of tissue culture are rarely available before 3 days and may take up to 10 days. A rapid diagnosis can be achieved by use of immunofluorescence on a smear of the lesion although this technology is only used in specialist centres. Alternatively, an acute blood sample (taken at time of presentation, day 1) and convalescent sample (taken after healing, day 7–10) can be used to demonstrate an increase in antibody titre to HSV-1.

Treatment is primarily palliative and includes bed rest and oral anti-inflammatory such as ibuprofen or paracetamol. It is essential that the patient maintains adequate fluid intake. Consideration should be given for the need to provide the patient with antiviral therapy. If the patient is otherwise healthy and symptoms are relatively mild then there is no requirement for an antiviral since it is unlikely to make any difference to recovery time. However, if the symptoms are severe or the patient is immunocompromised then it is wise to give systemic antiviral therapy.

There are relatively few antiviral agents compared to the number of antibacterial drugs that are available. The development of aciclovir led to the first specific antiviral agent. Aciclovir is a nucleoside analog drug that has activity against members of the herpes group of viruses, in particular HSV-1 and HSV-2. Aciclovir acts by blocking viral replication and therefore it is important to provide the drug at an early stage, preferably within 48 hours of the onset of acute symptoms. Two alternative antiviral agents used to treat infection caused by the HSV-1 or HSV-2 are penciclovir (available only in topical form) and famciclovir (the oral pro-drug of penciclovir).

The agent of choice for primary herpetic gingivostomatitis is aciclovir, preferably as a suspension since the tablet form is difficult to swallow in the presence of widespread oral ulceration. Aciclovir should be given at a dose of 200 mg, five times daily for 5 days. Children under the age of 2 years should receive a half-dose, while those over 2 years of age should receive the standard 200 mg dose.

Herpes labialis

Approximately a third of patients who have had primary herpetic gingivitis will subsequently suffer recurrent episodes of herpes labialis, also known as cold sores or fever blister, as a result of reactivation of latent HSV-1. There have been reports of the isolation of HSV-2 from recurrent herpes labialis but this is extremely rare. The recurrent lesions characteristically begin with a tingling or burning sensation (prodrome) in the vermillion border of the lip due to reactivation of latent virus in local neural tissues. In classic herpes labialis, a collection of painful intraepi-

thelial vesicles will develop within 24 hours at the site of the prodrome symptoms. However, approximately 25% of episodes have no prodromal stage and the lesion presents directly as vesicles. Within 48 hours the vesicles rupture and coalesce to leave erosions, which subsequently crust over (Fig. 29.107) and eventually heal within 7–10 days. The clinical appearance is so characteristic that diagnosis is based on this alone. However, if necessary, the presence of HSV, either type 1 or type 2, can be confirmed by isolation in tissue culture from a swab or the use of immunofluorescence on a smear of the lesion.

Factors that predispose to the development of herpes labialis in susceptible individuals include sunlight, trauma, stress, fever, menstruation, and immunosuppression. A sunscreen applied to the lips can be effective in reducing the frequency of sunlight-induced recurrences. A number of topical antiseptic or analgesic preparations, based on ammonia, povidone–iodine or lidocaine, are widely available to the general population for treatment of herpes labialis. However, these non-specific products are of limited proven benefit. Clinical trials have demonstrated that the topical application of an antiviral agent, either aciclovir or penciclovir, can reduce the duration of the outbreak and reduces viral shedding. Docosanol, an agent that alters the cell membrane to prevent viral entry, is also available for topical application for orofacial herpes simplex infections. Aciclovir, at a dose of 200 mg five times daily should be given systemically if herpes labialis develops near the eye (Fig. 29.108). Individuals with severe or frequent recurrences can benefit from the prophylactic use of systemic aciclovir taken at a dose of 200 mg three times daily for 6–9 months.

Fig. 29.107 Early scabbing stage of herpes labialis.

Fig. 29.108 Recurrent herpes simplex viral infection causing facial swelling and closure of the eye.

Recurrent herpetic ulceration

Reactivation of latent herpes simplex virus also produces intraoral ulceration. The hard palate is the site most frequently involved and the lesions present as a single localized crop of small shallow painful ulcers with surrounding erythema (Fig. 29.109). The outbreak may be preceded by prodrome symptoms of itching or pain similar to herpes labialis. Vesicles soon rupture to produce the characteristic ulcers which heal within 7–10 days. Whilst almost exclusively due to HSV-1, there is increasing evidence that HSV-2 can also cause this type of ulceration. This observation is probably due more to the frequent transmission of virus as a result of direct contact

Fig. 29.109 Reactivation of HSV-1 producing cluster of ulcers on hard palate.

during orogenital sexual practices but may in part also reflect the more widespread use of typing methods for suspected orofacial herpetic infections.

Chickenpox

Primary infection with varicella zoster virus (VZV) causes chickenpox, which occurs most frequently in childhood. The characteristic presenting clinical sign is a blistering skin rash on the abdomen. The skin lesions may occasionally be accompanied by the development of vesicles in the palate and faucial region, which rapidly rupture to produce small ulcers (2–4 mm). The diagnosis of chickenpox is usually made from the classic history and nature of the cutaneous lesions. Fluid from a skin blister can be sent for viral culture or a lesional smear examined using immunofluorescence to obtain definitive diagnosis. Treatment is supportive including a systemic antihistamine to reduce itching. Total resolution of symptoms will follow within 7–10 days. If the patient is immunocompromised then aciclovir at a high dose (800 mg five times daily) or standard doses of famciclovir (either 250 mg three times daily or 750 mg once daily) or valaciclovir (1 g three times daily) should be given. A vaccine for chickenpox is now available.

Herpes zoster (shingles)

Herpes zoster, which is also known as shingles, is caused by reactivation of latent VZV in sensory nerve ganglia. Most cases of herpes zoster affect the trunk and produce a unilateral horizontal band of skin lesions on the back and chest wall, restricted to one dermatome. When the trigeminal nerve is involved, which accounts for 10–15% of episodes of herpes zoster, it also manifests unilaterally in one division of the nerve. In the case of the maxillary or mandibular branch, the severe pain, which often precedes the skin and mucosal lesions by a few days, may be confused with toothache. However, once the characteristic distribution of vesicular lesions and mucosal erosions occurs (Fig. 29.110), the diagnosis of herpes zoster is usually obvious.

Although the diagnosis can be made on the basis of clinical presentation alone, confirmation of herpes zoster can be made by isolation of VZV in cell culture or immunofluorescence on a smear. Antiviral treatment should be given as early as possible, preferably within the first 48 hours of symptoms. Whilst in the past aciclovir was used for this infection, it is now

Fig. 29.110 Herpes zoster due to reactivation of VZV causing unilateral ulcerative lesions in the maxilla.

preferable to administer either famciclovir (250 mg three times daily or 750 mg once daily) or valaciclovir (1 g three times daily) due to the increased bioavailability of these antiviral drugs. Postherpetic neuralgia may subsequently be a major problem in these patients and therefore it has been recommended that antiviral therapy should be provided for at least 10 days to reduce the likelihood of this extremely painful condition. The symptoms of postherpetic neuralgia are extremely difficult to treat although some benefit may be gained by use of tricyclic antidepressant drugs and gabapentin. Topical application of capsaicin 0.075% cream three or four times daily has been reported to be of benefit in difficult cases.

Ramsay-Hunt syndrome

The development of a unilateral lower motor neuron facial nerve palsy (Fig. 29.111) combined with the appearance of a painful vesicular rash on the tympanic membrane and external auditory canal on the same side is termed Ramsay-Hunt syndrome. It has been proposed that this situation develops as a result of reactivation of varicella zoster virus in the region of the geniculate ganglion of the facial nerve. The clinical diagnosis can be supported by detection of VZV in the fluid of the vesicles. Treatment consists of provision of standard zoster doses of an antiviral (valaciclovir or famciclovir) to limit viral replication combined with prednisolone (typically 20–30 mg daily) to reduce inflammation. Therapy should be continued until the symptoms resolve, which is usually within 14 days.

Infectious mononucleosis (glandular fever)

Infectious mononucleosis, also known as glandular fever, is characterized by the onset of a painful throat and submandibular lymphadenopathy, which may occasionally be accompanied by fine petechial hemorrhages in the hard and soft palate. In addition, a white pseudomembrane may develop on the tonsils. This condition is caused by infection with Epstein-Barr virus (EBV), probably as a result of kissing.¹⁸⁶

Fig. 29.111 Facial nerve palsy.

Diagnosis is confirmed by demonstration of a lymphocytosis and atypical mononuclear cells (Downey cells) in a blood film or, alternatively, by detection of heterophile antibodies ("Monospot test"), EBV-specific antibody (immune-fluorescence) or EBV DNA (by polymerase chain reaction (PCR)). Treatment is supportive and includes bed rest. Ibuprofen or paracetamol is helpful in relieving the symptoms of sore throat. Approximately 70% of adults acquire the virus by the age of 30 years and periodically shed it in the saliva without symptoms.

Hairy leukoplakia

Oral hairy leukoplakia was first described in 1984 as a non-painful corrugated white lesion on the lateral border of the tongue in HIV-positive individuals (Fig. 29.112).^{187,188} Whilst originally only seen in HIV disease, a case was described in 1999 in an HIV-negative acute leukemia patient and subsequently in recipients of solid organ transplants.^{189,190} Furthermore, it has also been described at non-lingual sites such as the buccal mucosa (Fig. 29.113). Whilst described as "hairy", the appearance of the side of the tongue is often more corrugated. Diagnosis is confirmed by demonstration of EBV in lesional tissue using *in situ* hybridization with appropriate DNA probes. The exact role of EBV in hairy leukoplakia remains uncertain. Imprint cultures of hairy leuko-

Fig. 29.112 Hairy leukoplakia on the lateral margin of tongue.

Fig. 29.113 Hairy leukoplakia presenting as a white patch in the buccal mucosa.

plakia often yield candidal species, but it is likely that this represents opportunistic secondary infection rather than a primary etiologic factor.

Hairy leukoplakia does not require specific treatment unless causing discomfort or esthetic problems. Systemic aciclovir (800mg five times daily) or preferably ether valaciclovir (1g three times daily) or famciclovir (500mg times daily) should be given over 2 weeks. Unfortunately, the lesions often recur a few months after the antiviral therapy. The topical application of podophyllin resin (25% solution) or retinoic acid has been described, but this is also of limited benefit due to recurrence. Small localised lesions can be excised surgically. In addition, the application of cryotherapy has been reported but is not widely employed.

Burkitt's lymphoma

Burkitt's lymphoma is named after the surgeon Denis Burkitt, who in 1958 mapped the geographical distribution of this condition across Africa.¹⁹¹ This aggressive rapidly growing B-cell tumour has two major forms, the endemic (African) form and the non-endemic (sporadic) form. The African form most frequently presents as a swelling of either the mandible or maxilla with mobility of the teeth and cervical lymphadenopathy in childhood. There is a strong association with EBV in the African form but its role in the sporadic form elsewhere in the world is less clear. Chemotherapy should be started as soon as possible but unfortunately the outcome remains poor, especially in later stages, and death often occurs rapidly after diagnosis.

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma is a relatively rare tumor but is seen more frequently in China and South-East Asia.¹⁹² Patients will present with difficulty in breathing or speaking and complain of swelling in the throat, bleeding from the nose, and earache. The spread of extensive lesions will be visible in the posterior oropharynx (Fig. 29.114). There is a direct asso-

Fig. 29.114 Extensive squamous cell carcinoma in posterior oropharynx.

ciation with this cancer and EBV. Radiotherapy is the treatment of choice, together with chemotherapy in advanced cases.

Roseola infantum

This acute and extremely common condition of childhood is characterized by mild fever and a skin rash on the body that last only a few days. Whilst the skin rash does not affect the face, erythematous papules in the soft palate and uvula, sometimes referred to as Nagayama's spots, may be observed. The intraoral lesions are thought to be caused by human herpes virus type 6. Diagnosis is made on clinical grounds and no active treatment is required since the condition is self limiting.

Kaposi's sarcoma

Kaposi's sarcoma was first described by Moritz Kaposi, a Hungarian dermatologist, in 1872.¹⁹³ The original cases presented as multiple pigmented papular lesions on the skin of elderly men in the Mediterranean region or of Eastern European descent. It received particular attention in the 1980s when a high incidence was observed in association with HIV infection and subsequently other immunosuppressed patients (Fig. 29.115). The mouth is the initial site of involvement in 15% of AIDS-related cases. The hard palate is the most frequent site, although it may also arise on the gingivae. This tumor is not a true sarcoma but a proliferation of lymphatic endothelial cells. The lymphatic channels fill with blood to give the classic appearance of a bruise in the early stages, then a dark swelling. Human herpes virus 8 has been encountered in all forms of Kaposi's sarcoma and is believed to be the etiologic agent of this condition.¹⁹⁴ Small lesions can be excised whilst larger ones may be treated with either low-dose radiotherapy or by the injection of a chemotherapeutic drug, such as vinblastine. Extensive or multiple lesions may require the provision of systemic chemotherapy.

Fig. 29.115 Kaposi's sarcoma presenting as a typical pigmented lesion in the hard palate.

Hand, foot, and mouth disease

Hand, foot, and mouth disease acquired its name from the characteristic distribution of lesions (Figs 29.116, 29.117, and 29.118), that present as bright red macular or vesicular eruptions on the skin of the hands and feet and mucosa of the pharynx, soft palate, buccal sulcus or tongue. The development of oral lesions is preceded by facial pain. The signs and symptoms are transient and last less than 3 days. This condition is often caused by the highly infectious

Fig. 29.116 Hand, foot, and mouth disease presenting as vesicular lesions on the fingers in combination with ulceration of the oral mucosa.

Fig. 29.117 Hand, foot, and mouth disease presenting as vesicular lesions on the toes in combination with ulceration of the oral mucosa.

Fig. 29.118 Hand, foot, and mouth disease presents as vesicular lesions on the fingers and toes in combination with ulceration of the oral mucosa.

enterovirus, Coxsackie virus subspecies A16. However, Coxsackie virus types A4, A5, A9, and A10 have also been isolated from patients with this condition. The diagnosis of hand, foot, and mouth disease is usually made on the basis of the characteristic clinical signs. Culture of Coxsackie viruses is not widely available and therefore if confirmatory diagnosis is required this has to be based on demonstration of increased levels of specific antibody in acute and convalescent blood samples. Treatment is supportive and antimicrobial agents are not required.

Herpangina

Herpangina occurs predominantly in children, and presents as sudden onset of fever and sore throat with subsequent development of papular, vesicular lesions on the oral mucosa and within the pharynx. Coxsackie virus subspecies A2, A4, A5, A6, and A8 have all been isolated from patients with herpangina. The severity of symptoms is variable, but clinical resolution usually occurs within 7–10 days. The diagnosis of herpangina is usually made on the basis of the characteristic clinical signs and symptoms. If definitive diagnosis is required this has to be based on demonstration of increased levels of specific antibody in acute and convalescent blood samples. Treatment consists of bed rest and the use of an antiseptic mouthwash, such as 0.2% chlorhexidine gluconate two or three times daily. Patients should be encouraged to maintain adequate fluid intake.

Verruca vulgaris

Verruca vulgaris, also known as oral warts, present most frequently as one to four small localized growths on the labial or lingual mucosa (Fig. 29.119). Involvement of the mouth is often associated with lesions on the fingers which may act as a source of the causative human papilloma virus (HPV), usually HPV type 2 or HPV type 4. Alternatively, the oral lesions may arise from orogenital contact, where HPV types 6, 11, and 16 are more prevalent. The clinical appearance is characteristic, but diagnosis can be

confirmed by histopathologic findings of excisional biopsy tissue. Immunostaining will determine the presence of the particular type of papilloma virus type. Excision is usually curative and recurrence is uncommon except in immunocompromised individuals.

Verruca vulgaris is a benign tumor, but in recent years there has been increasing interest in the potential role of HPV 16 in the etiology of oropharyngeal carcinoma as a result of oral sexual practices.¹⁹⁵ Further evidence of the involvement of HPV 16 in this situation would support vaccination against this virus. The recognized association of this virus in cervical cancer has led to the proposal that all females are vaccinated against HPV 16 at the age of 12 years.

Focal epithelial hyperplasia (Heck's disease)

Heck's disease is a rare condition that is characterized by the development of multiple smooth-topped pink papules on the buccal mucosa, labial mucosa, tongue, and gingivae (Fig. 29.120). Molecular methods and epidemiologic studies have supported the involvement of HPV types 13 and 32 in this condition.¹⁹⁶ It was first described in Native Americans and the Inuit but has also been described in other populations. No active treatment is required although larger lesions can be surgically removed if causing esthetic problems or local symptoms.

Mumps

Mumps (endemic parotitis) classically presents as painful swelling of either one or both of the parotid glands. However, other major salivary glands may also occasionally be involved. Other frequent features include sore throat, earache, and pain on chewing. The orifice of the parotid duct may appear erythematous with reduced salivary flow. The differential diagnosis of acute suppurative sialadenitis can be made by the absence of a purulent discharge.

Fig. 29.119 Two localized lesions of verruca vulgaris on the ventral surface of the tongue.

Fig. 29.120 Multiple localized epithelial swellings in Heck's disease.

Complications include meningoencephalitis and orchitis in about a third of cases or more rarely myocarditis and nephritis. This condition is caused by an enveloped RNA paramyxovirus that initially infects circulating T lymphocytes that subsequently infect salivary duct epithelial cells.

Diagnosis can usually be made on the basis of clinical symptoms. However, if there is doubt then serologic investigation to demonstrate the presence of specific IgM antibody can be used. In addition, a sample of saliva, collected by cannulation of the parotid duct, can be examined by electron microscopy for virus particles. Treatment is supportive and antibiotic therapy is not required. The MMR (mumps, measles, and rubella) vaccine provides immunity.

Measles

Measles is a common and highly infectious disease of childhood that presents as an acute exanthematous skin rash and fever. The patient is likely to develop conjunctivitis, nasal discharge, headache, and sore throat. The extraoral signs may be accompanied by transient small discrete macules in the buccal mucosa (Koplik's spots), the appearance of which may aid diagnosis. Definitive diagnosis involves serologic detection of measles IgM antibody or isolation of measles RNA from a nasal swab or sputum. Treatment is supportive and most patients will recover without problems. However, it must be remembered that this infection may be fatal, especially in malnourished states or immunocompromised individuals. The MMR (mumps, measles, and rubella) vaccine provides immunity but in areas of low uptake or non-availability of the vaccine, measles still presents a serious illness due to potentially life-threatening bronchopneumonia or encephalomyelitis. In Saharan Africa, the virus has also been implicated in gross destruction of the orofacial tissues (noma) in malnourished individuals.¹⁹⁷

Acknowledgments

We would like to thank Dr M. Nakada (Department of Neurosurgery, Graduate School of Medical Science, Kanazawa University), Dr T. Miwa, Dr M. Ito (Department of Otorhinolaryngology, Graduate School of Medical Science, Kanazawa University), Dr F. Ueda (Department of Radiology, Graduate School of Medical Science, Kanazawa University), Professor E. Yamamoto, Dr S. Kawashiri, Dr K. Nakagawa (Department of Oral and Maxillofacial Surgery, Graduate School of Medical Science, Kanazawa University), Professor K. Watanabe (Division of Anaerobic Research, Life Science Research Center, Gifu University), and Professor H. Sakamoto (Department of Oral Surgery, Tokai University Hachioji Hospital) for their helpful sug-

gestions. Our thanks also go to Dr T. Aoki (Department of Oral Surgery, Tokai University), Dr A. Kanekawa (Division of Oral and Maxillofacial Surgery, Yamaguchi Grand Medical Center), Dr T. Sugiura (Department of Oral Surgery, Yamanobe Hospital), Miss T. Tanbo (Department of Oral and Maxillofacial Surgery, Graduate School of Medical Science, Kanazawa University) and Dr S. Takatsuka (Department of Oral and Maxillofacial Surgery, Kanazawa University Hospital) for providing photographic images, Miss H. Matsumoto (Department of Oral and Maxillofacial Surgery, Graduate School of Medical Science, Kanazawa University) for her kind help in collecting materials for this chapter, and J. G. Cowpes (Cardiff University) for proofreading.

Chapter 30

Initial Evaluation and Management of the Oral and Maxillofacial Pathology Patient

Allen Cheng and Brian L. Schmidt

In this chapter, the following topics are covered:

- How to take an adequate history and carry out an examination for a pathological lesion in the oral cavity and related structures.
- Current imaging techniques for further defining pathological lesions of the head and neck.
- The principles of biopsy for oral and related lesions including incisional biopsy, excisional biopsy, and fine needle aspiration. Biopsy techniques applicable to different oral sub-sites are described.
- Adjunctive diagnostic techniques including toluidine blue, brush technique, VELscope®, and chemiluminescents.
- The diagnosis and management of dysplasia and other premalignant lesions.

Approaching the oral and maxillofacial pathology patient, 586

Obtaining the history, 586

The focused physical examination, 586

Imaging studies, 593

Obtaining a tissue diagnosis, 596

Fine-needle aspiration biopsy, 599

Open biopsy for lymphadenopathy, 602

Summary of the approach to the oral and maxillofacial pathology patient, 602

Adjunctive diagnostic tools, 603

Toluidine blue, 604

Tissue fluorescence, 604

Tissue reflectance, 606

Brush cytology, 606

Management of premalignant disease, 607

Natural history of premalignant disease, 608

Genetic progression to oral cancer, 609

Surgical management of dysplasia, 609

Medical management of dysplasia, 610

Summary of management of dysplasia, 610

Margin assessment, 610

Frozen section analysis, 610

Tissue shrinkage in margin analysis, 611

In seeking absolute truth we aim at the unattainable and must be content with broken portions.

Sir William Osler

Oral cancer is an uncommon disease. Despite being the sixth most common malignancy in the world,¹ it is a clinical rarity in most practices. Maybe because of the low incidence of oral cancer, the diagnosis and treatment of it are relegated to a few with interest in this esoteric field. However, this also means that many providers, whether they are primary care physicians, dentists, oral and maxillofacial surgeons, otolaryngologists, or pathologists, do not feel adequately equipped to diagnose oral cancer. Patients are often unaware that such cancers exist. A direct consequence of this common inexperience is that patients with oral cancer have a significant delay in

diagnosis from initial presentation to evaluation by a specialist, leading to diagnoses when tumors are advanced in stage.² A delay in diagnosis contributes to the relatively poor prognosis of oral cancer, which is disturbing given that oral cancer involves an anatomic location that can be evaluated by direct visual and tactile examination.^{3,4}

The purposes of the first part of this chapter are to provide an overview of the diagnostic armamentarium available for oral cancer and to then outline a basic algorithm for management of suspicious oral lesions. The second part of the chapter will discuss the methods and shortcomings of surgical pathology with the intent to provide a framework for which the surgeon may best assist the pathologist in making the correct diagnosis and then subsequently interpret the pathologist's report.

Approaching the oral and maxillofacial pathology patient

The first step to approaching a patient with oral and maxillofacial pathology is to take a thorough history and perform a physical examination. Information gleaned from the history and physical examination will provide clues to the correct diagnosis and guide the clinician in selecting the appropriate tools to validate the diagnosis.

Obtaining the history

In taking the history of present illness, one should first establish a timeline for the disease. One should ask when the patient first noticed symptoms. Symptoms of interest include pain, paresthesia, dysphagia, dyspnea, otalgia, trismus, voice changes, weight loss, fevers, chills, and malaise. Although not necessarily present, pain is the most common presenting symptom for head and neck cancer.^{4,5} Paresthesia in the head and neck area is also highly concerning, and should be considered a sign of potential malignancy until proven otherwise. Either of these symptoms, when occurring without a likely explanation, should prompt a thorough investigation including a neurologic exam, imaging studies, and, potentially, tissue sampling.

The surgeon should inquire about any prior treatment or diagnostic tests. If biopsies have been performed in the past, it is essential to review both the pathology report and the pathology slides. One should not take a prior pathologic diagnosis at face value, as errors may have occurred at any point from the biopsy, to the receipt of the specimen by the pathologist, to the final report. In addition, because oral cancer and other oral neoplasms are relatively rare, it is important to have slides reviewed by pathologists with experience in diagnosing disease in the head and neck region. Given the gravity of a diagnosis of oral cancer, validation is warranted.

Other diseases, such as infectious diseases and autoimmune diseases, may present with oral lesions similar to oral cancer. Ask about symptoms that can rule in or out these other diseases if the initial history is suggestive of pathology other than cancer. The patient's history should be reviewed for exposures, constitutional symptoms, or systemic manifestations. An acute onset, presence of fever or chills, rapid swelling, and signs of acute inflammation are suggestive of an infectious process. A chronic process with dermatologic findings, arthralgias, or multiple organ system involvement is suspicious for an autoimmune disorder.

The clinician should take the time to take a thorough past medical history. The history may provide additional information helpful for stratifying a patient's risk for developing oral cancer. The past medical history may provide the etiology of the

disease. Inquire about a history of dysplasia, immunocompromised states, other types of cancer, and a history of head and neck radiation.

A history of tobacco and alcohol use should be determined. Ask about cigarette usage in addition to other forms of tobacco use, such as snuff, cigar, or pipe tobacco. The quantity of tobacco and length of time used should be recorded. An accurate alcohol history is often difficult to gather, as most people underestimate their use. It is helpful to corroborate history with family and friends. It is also helpful to inquire about betel nut use, particularly in patients of Asian or South Asian descent. One should inquire about environmental exposures at work and home. A history of dental neglect should be recorded.

The focused physical examination

The focused examination of the oral and maxillofacial pathology patient should always include an examination of the neck, the face, the salivary glands, and the oral cavity. Examination of the eyes, ear, nose, pharynx, larynx, and cranial nerves should be performed as directed by the patient's presenting symptoms and the clinician's differential diagnosis. The following section will briefly describe some of the more critical aspects of the physical examination. However, it is beyond the scope of this chapter to fully detail all the nuances of the physical exam of the head and neck.

Neck

The focused exam should begin with a careful examination of the neck. All levels of the neck should be palpated for lymphadenopathy. Fig. 30.1 illustrates the different levels of the neck. However, the actual sensitivity of physical exam for detecting metastatic nodes is low.⁶ Regardless, this provides the basis for clinical staging and subsequent treatment planning. Neck swellings that are palpable should be described by location, size, tenderness to palpation, temperature, compressibility, texture, fluctuance, induration, whether the swelling is freely mobile in vertical and horizontal planes or is fixed to underlying tissues, and whether there are changes in the overlying skin. In certain cases, transillumination may aid in determining whether the lesion is fluid filled. If in the midline, the swelling should be evaluated while the patient is swallowing. Swellings that rise and fall with swallowing are likely thyroglossal duct cysts. Swellings that are pulsatile, have a palpable thrill, or have a bruit on auscultation, may be indicative of a vascular lesion.

Thyroid gland

The thyroid gland is located inferiorly, in the anterior compartment of the neck, situated just inferior to the level of cricoid cartilage. The gland is comprised of

Fig. 30.1 Illustration of the levels and sublevels of the neck. Notice that level II is divided into IIA and IIB by the spinal accessory nerve and level V is divided into VA and VB by a horizontal plane from the inferior border of the cricoid arch. Illustration from Cheng and Schmidt, used with permission.

two lobes that extend laterally and are connected medially by a central isthmus. Occasionally, there is a third pyramidal lobe that extends superiorly along the midline. Examination of the thyroid gland can be performed from behind or facing the patient. The exam is performed one lobe at a time. One hand is used to stabilize the lobe contralateral to the one being examined by placing the fingers of the opposite hand firmly into the contralateral tracheal–esophageal groove. The examining hand then palpates the lobe of interest, taking note of size, texture, and nodularity. The exam is then repeated on the contralateral lobe. A normal thyroid gland may be difficult to discern, especially in patients with significant soft tissue redundancy. As mentioned above, having the patient drink water while palpating the gland can help with defining its location, as the thyroid gland should elevate with swallowing.

Face

The skin of the scalp, neck, and face should be examined carefully for lesions or masses. Hair should be parted in order to adequately inspect the scalp. Any asymmetries in the face should be noted. The facial skeleton should be palpated for expansion or tenderness.

The temporomandibular joint should also be assessed. This can be performed by palpating the preauricular area while asking the patient to open and close. Any tenderness to palpation is abnormal and should be documented. The examiner should note any clicks, popping, crepitus, or tenderness, and whether the findings are unilateral or contralateral.

The examiner should also make note of the timing of the findings, whether they occur with jaw opening, closing, or both, and whether they are early or late along the arc of opening or closing. The examiner should ask the patient to move their lower jaw to the right, to the left, and forward, to evaluate the patient's excursive and protrusive function. If there are any limitations in movement, the examiner should record the maximal incisal opening and maximum range of excursive and protrusive movements. Normal maximal incisal opening is considered to be in the range 53–58 mm. Neoplasms of the temporomandibular joint, ramus of the mandible, and lateral pharyngeal space can all cause limitation of movement and pain, although temporomandibular disorders are more frequent causes for these symptoms.

Parotid and submandibular glands

The parotid and submandibular glands should be evaluated for nodules, swelling, tenderness, warmth, erythema, or changes in the overlying skin. It is important to remember that the tail of the parotid extends to a level inferior to the angle of the mandible and swelling of the deep lobe of the parotid may manifest as a mass in the lateral pharyngeal wall, so examination of these areas is necessary. There are several lymph nodes located within and around the parotid tissue that receive lymphatic drainage from the skin of the upper face, mid face, and parts of the scalp. While palpating, be sure also to palpate for the pre-auricular and retroauricular nodes.

Eye

When indicated, the eyes should be examined for symmetry, pupillary reflex, and function of extraocular muscles. The palpebra, conjunctiva, and lacrimal ducts should be inspected. Dry and injected conjunctiva is a finding common to several autoimmune syndromes. Any discrepancy with alignment of the eyes should be documented. Tumor involvement of the maxillary sinus may cause vertical dystopia, as shown in Fig. 30.2. Involvement of the posterior orbit can also manifest as exophthalmos due to mass effect. If excessive epiphora is present, this should also be recorded. If the recent history includes a complaint of change in vision or ocular pain, a fundoscopic exam should be performed to rule out intraocular pathology.

Ear

If the patient's presentation includes symptoms of otalgia, hearing changes, vertigo, ear "stiffness", facial paralysis, or unexplained facial pain, an examination of the ear should be performed. Ear stiffness is a common presenting complaint in patients with nasopharyngeal carcinoma, which is of particular concern among patients of Chinese descent. The clini-

Fig. 30.2 A 2-year-old boy with an aggressive poorly differentiated spindle cell tumor. Notice the vertical dystopia and increased scleral show caused by elevation of the left orbit due to tumor mass effect.

cian should keep this in mind when a Chinese patient complains of epistaxis and ear stuffiness. The examination of the ear begins with careful inspection of the auricle, as auricular neoplasms can be easily missed in the posterior auricular area or within the concha or antihelix. The mastoid should be evaluated for signs of mastoiditis, a complication of otologic infections.

An otoscope should be used to examine the external auditory meatus, tympanic membrane, and middle ear. With the clinician facing the ear to be examined, the posterior hand should grasp the posterior–superior pinna and retract in the posterior direction. This maneuver straightens the external auditory meatus. The otoscope is carefully inserted into the canal with the anterior hand, resting on the patient's ipsilateral shoulder as a fulcrum. Cerumen disimpaction may be necessary for adequate visualization of the proximal ear. Many otoscopes allow the magnifying lens to be removed so that a curette may be introduced into the canal for removal of cerumen. Great care should be taken when doing this as the external auditory meatus is richly innervated.

If the chief complaint includes ipsilateral facial paralysis, the auricle and external auditory meatus should be inspected for vesicles or ulcers. Herpes zoster or herpes simplex of the ear is related to Ramsay-Hunt syndrome, a cause of Bell's palsy. In otitis externa, gentle traction of the auricle can be quite painful. The external auditory meatus can be quite edematous and inflamed. The tympanic membrane should be inspected carefully for perforation or fluid (which may be serous, cloudy, or bloody) behind the membrane. These may be signs of otitis media. However serous otitis may also be a sign of eustachian tube obstruction from tumor involvement. Weber and Rinne tests should be performed if indicated by a complaint of hearing loss or stuffiness.

Nasal cavity and nasopharynx

If the patient is complaining of epistaxis or nasal stuffiness, a nasal examination may be indicated. A nasal speculum with a good light source can be used to examine the anterior nasal cavity. Attention should be paid to the mucosa of the lateral and medial walls. Any ulcers, masses, or lesions should be noted. Kiesselbach's plexus, which is the anastomosis of the anterior ethmoidal, greater palatine, sphenopalatine, and superior labial arteries, is the most common site for epistaxis. Allergic rhinitis is typified by pale, boggy, and edematous mucosa. Infectious sinusitis manifests as erythematous edematous mucosa.

If examination of the posterior nasal cavity or nasopharynx is required, as is the case when there is clinical suspicion of nasal or nasopharyngeal carcinoma, this can be performed using endoscopy under local anesthesia. Following administration of local anesthesia and a decongestant spray, with the patient in a sitting position with chin lifted slightly upward, a flexible or rigid endoscope may be introduced along the floor of the nasal cavity. The examiner should make the effort to visualize the nasal septum, inferior turbinate, and opening of the eustachian tube with this initial pass. The endoscope is then repositioned above the inferior turbinate so that the middle turbinate comes into view. To examine the nasopharynx, a flexible endoscope is passed along the floor of the nasal cavity posteriorly and angled inferiorly into the nasopharynx, taking care to fully visualize both the right and left pharyngeal walls by rotating the scope. The nasopharynx may also be indirectly visualized with adequate lighting by placing a hand mirror into the oropharynx, posterior to the soft palate. Contact with the tongue base should be avoided. Heating the mirror with warm water can help prevent fogging of the reflective surface.

Oral cavity and oropharynx

When examining the oral cavity, the buccal mucosa, vestibular mucosa, alveolar mucosa and gingiva, the palatal mucosa, lingual mucosa, the floor of mouth, and all borders of the tongue should be inspected both visually as well as by palpation. If the patient is wearing any removable dental prostheses, these should always be removed prior to inspection. Special attention should be paid to inspecting the posterior lateral tongue and the floor of mouth as they are the two most common sites for oral cancer. When examining the oral tongue, it may be necessary to grasp the tongue with a square of gauze and retract it anteriorly in order to fully visualize the posterior–lateral aspect of the tongue. Tongue and floor of mouth mobility should be assessed. Any tethering of the tongue or floor of mouth should be noted and may be indicative of a neoplastic process. The floor of mouth should be palpated bimanually, particularly in the lingual gutter. Examination of the maxilla and mandible should

be done by bimanual palpation to assess for swelling or cortical expansion. The characteristics of any swelling should be described. If glandular pathology is suspected, salivary function should also be assessed. This can be performed by using gauze to dry the mucous membranes around the parotid duct or submandibular duct, and then palpating the gland to promote salivation. The quantity and character of the salivary flow should be noted.

As an oral and maxillofacial surgeon, one should also take a moment to do a cursory dental exam, making note of any teeth with questionable prognoses. If radiation therapy is to be considered, then extraction of compromised teeth could be performed at the same time as the ablative surgery to prevent delays in treatment. It is important to measure the maximal incisal opening, as well as make note of the Angle's classification for the patient's occlusion, the position of the maxillary and mandibular dental midlines, and reproducibility of the patient's occlusion. This information will play a critical role in the reconstructive phase of any surgical treatment for malignancy provided.

The oropharynx is best examined directly by retracting the tongue anteriorly using tongue blades or gauze under adequate lighting. The tongue can be moved to bring the lateral aspects of the posterior third of the tongue into view. Palpation is used to assess this area for potential lesions. While retracting the tongue, visually inspect the soft palate, anterior and posterior tonsillar pillars, and uvula. A dental mirror can then be used to indirectly examine the lateral pharyngeal walls, the posterior pharyngeal walls, and the vallecula.

Larynx

An examination of the larynx is indicated if the patient presents with neck swelling concerning for nodal metastasis with no observable primary lesion or the patient who presents with changes in their voice, dysphagia, odynophagia, or airway obstruction. The examination can be done indirectly, using a dental mirror placed in the oropharynx, or directly with an endoscope.

To perform an indirect exam, have the patient sit in the exam chair, leaning forward slightly with chin tilted upward to allow for adequate illumination of the posterior oropharynx. As with examining the oropharynx, the tongue is retracted by grasping the anterior two thirds firmly with gauze. A warmed dental mirror is placed posteriorly with the backside gently retracting the uvula and soft palate superiorly. If the patient has a strong gag reflex, it is advisable to spray the soft palate with a topical anesthetic before performing the exam. Once the mirror is in place, it can be adjusted to bring the larynx into view.

A direct exam with a flexible endoscope provides improved visualization if the equipment is available. Similar to nasal endoscopy, after local anesthesia is

administered and the patient is positioned properly in a sitting position leaning slightly forward, a flexible scope is passed along the floor of the nasal cavity. The tip of the endoscope is placed above the epiglottis, from which the larynx should come into view.

The epiglottis, aryepiglottic folds, false vocal cords, ventricles, true vocal cords, and arytenoids should be studied for erythema, masses, or ulcerations. In addition, the true vocal cords should be examined while the patient is quietly breathing, breathing heavily, and phonating to assess for symmetry of cord adduction and abduction. If there is any incompetence of the vocal cords, such that the folds do not fully adduct, this should be noted.

The subglottic area can be viewed through the aditus while the true vocal cords are abducted. However, for a complete exam of the subglottic area, endoscopy under general anesthesia may be required.

Cranial nerves

A gross cranial nerve exam should be performed if the patient complains of any sensory or motor deficit. As mentioned above, any sign of paresthesia is highly suspicious of perineural invasion. For the initial consultation, the cranial nerve exam of the oral and maxillofacial pathology patient typically focuses on the sensory components of the trigeminal nerve and the motor components of the facial nerve. The distributions of the trigeminal nerve should be stimulated, looking for paresthesia or dysesthesia that can be localized. Similarly, the different branches of the facial nerve (temporal, zygomatic, buccal, marginal mandibular, and cervical) should be assessed to attempt to localize the nerve involvement. Details of the gross cranial nerve exam are described in Table 30.1.

In performing a focused history and physical exam for the head and neck pathology patient, it is essential for each clinician to establish a defined order so they can perform the history and physical exam systematically, in order to avoid inadvertently omitting any part. Also, the clinician should keep in mind the old adage that one cannot see what one does not know, and always keep considering the differential diagnosis. As soon as the patient-doctor interaction begins, the experienced clinician is already formulating a differential diagnosis and testing his or her hypotheses. This evolving differential is what drives the nature of further examinations and testing. Tables 30.2 and 30.3 outline the differential diagnosis for lesions within the oral cavity.

Conventional oral examination as a screening tool

The purpose of a screening tool is to detect disease in patients who are asymptomatic in the hopes of improving prognosis by early intervention. In order to be effective as a screening tool for oral cancer, the

Table 30.1 Focused examination of the cranial nerves.

	Cranial nerve	Examination
I	Olfactory nerve	Occlude one nostril, test the patency, then have the patient identify distinct smells, such as coffee or peppermint
II	Optic nerve	Check visual acuity of each eye separately using Snellen chart Check afferent limb of pupillary reflex by briefly shining a light into each pupil Perform the swinging light test to check for the consensual reflex
III	Oculomotor nerve	Check full range of extraocular muscle movements by having the patient follow your finger to six positions: right, right and up, right and down, left, left and up, left and down The oculomotor nerve is responsible for superior medial, superior lateral, medial, and inferior lateral gaze Check efferent limb of pupillary reflex as above
IV	Trochlear nerve	Check full range of extraocular muscle movements as above The trochlear nerve is responsible for inferior medial gaze
V	Trigeminal nerve	Test for sensation of the face in the three main branches of the trigeminal nerve by lightly touching the skin on each side of the face with the patient's eyes closed
VI	Abducens nerve	Check full range of extraocular muscle movements as above The abducens nerve is responsible for lateral gaze
VII	Facial nerve	Test for symmetrical activity of the muscles of facial expression in the upper, middle, and lower face Have the patient raise the eyebrows, tightly close the eyes, smile, and grimace
VIII	Vestibulocochlear nerve	Test gross hearing by gently rubbing strands of hair between your fingers adjacent to each ear and asking the patient if it is audible Vestibular function can be tested by performing the Dix-Hallpike test or Romberg test
IX	Glossopharyngeal nerve	Test for function of the stylopharyngeus muscle by having the patient phonate "Ah" and watch for symmetrical elevation of the soft palate and uvula
X	Vagus nerve	Test the function of the palatal and pharyngeal muscles along with testing the glossopharyngeal nerve, as described above
XI	Accessory nerve	Test the spinal accessory nerve by asking the patient to turn the head left and right against resistance and shrug the shoulders against resistance
XII	Hypoglossal nerve	Test by having the patient protrude the tongue and watching for deviation Have the patient press the tongue against each cheek against resistance from your hand against the patient's cheek

method must be sensitive enough to detect most tumors and find them early enough so that intervention improves survival. Furthermore, the tool must be specific enough that patients without cancer would not be subjected to unnecessary invasive testing and treatment. The screening tool should be safe and simple to perform. Finally, it is desirable that the screening tool leads to a reduction in mortality in the population that the tool is intended to target.

The conventional oral examination is the standard tool for screening for oral cancer and is the only such tool that has been properly studied for this purpose. The advantages of the conventional oral examination are that it can be easily performed by non-specialists, it is inexpensive, and it is non-invasive.

However, conventional oral examination effectiveness in detecting cancer when used by the generalist and its ability to reduce mortality in the population is controversial. Several studies do support its use. Jullien *et al.*, in a large oral cancer screening program that enrolled 2300 patients, demonstrated that general dentists were able to effectively identify suspicious lesions (defined as red, white, or ulcerative lesions of 2 weeks' duration) with a sensitivity and specificity of 74 and 99% respectively when compared to oral cancer specialists.⁷ The same group

performed a review of the literature, which included four studies evaluating dental auxiliaries as screeners, and found sensitivities and specificities ranging from 73–92% and 93–98% respectively.⁸ It is important to note that the lesions in the above studies were not confirmed by biopsies to be malignancies.

In terms of its ability to reduce mortality in the population, one large cluster-randomized controlled trial in Kerala, India, which enrolled 96517 patients over the course of 9 years, demonstrated an earlier stage at time of diagnosis and improved 3-year survival;^{9,10} as well as showing improved mortality rates in high-risk groups, namely male tobacco and alcohol users.¹¹ Although this study has been criticized for not addressing lead time bias in its analysis and not meeting standards set by the Cochrane Collaboration for cluster-randomized trials, its significance in demonstrating survival benefits by the use of a simple tool in an at-need population cannot be overlooked.

Although conventional oral examinations are effective in detecting suspicious lesions, only a minority of these lesions will ultimately turn out to be cancer. On the other hand, mucosa that appears clinically normal may actually have microscopic evidence of neoplasia. Thomson found that 36% of the patients in

Table 30.2 Differential diagnosis of oral lesions by appearance of lesion. The lesions are listed in order of frequency. The locations in the oral cavity are listed in order of frequency.

Diagnosis	Location in oral cavity
White lesions that can be wiped off	
White coated tongue	Dorsal tongue
Pseudomembranous candidiasis	Buccal mucosa, tongue, palate
Frictional hyperkeratosis	Buccal mucosa, lips, tongue
Thermal injury	Lip, palate, buccal mucosa
Chemical injury	Buccal mucosa, gingiva
Secondary syphilis	Tongue, lip, buccal mucosa, palate
Diphtheria	Oropharynx
White lesions that cannot be wiped off	
Linea alba	Bilateral buccal mucosa
Leukoedema	Bilateral buccal mucosa
Leukoplakia	Buccal mucosa, lip, gingiva, tongue, floor of mouth
Snuff dipper's pouch keratosis	Mandibular vestibule
Actinic keratosis	Lower lip
Lichen planus	Bilateral buccal mucosa, tongue, gingiva, palate, lip
Frictional hyperkeratosis	Buccal mucosa, lip, tongue
Nicotine stomatitis	Hard palate
Hairy leukoplakia	Lateral tongue
Hyperplastic candidiasis	Buccal mucosa
Lupus erythematosus	Buccal mucosa, palate, gingiva
Submucous fibrosis	Bilateral buccal mucosa
White sponge nevus	Bilateral buccal mucosa, tongue, lip, palate, gingiva, floor of mouth
Tertiary syphilis	Palate, tongue
White and red lesions	
Erythema migrans (geographic tongue)	Tongue
Erosive candidiasis	Buccal mucosa, tongue, palate
Erosive lichen planus	Bilateral buccal mucosa, tongue, gingiva, palate, lip
Erythroleukoplakia	Buccal mucosa, lip, gingiva, tongue, floor of mouth
Lupus erythematosus	Buccal mucosa, palate, gingiva
Scarlet fever	Tongue, pharynx
Red lesions	
Viral pharyngitis	Oropharynx
Bacterial pharyngitis	Oropharynx
Denture stomatitis	Palate
Erythematous candidiasis	Tongue, palate, alveolar mucosa
Erythroplakia	Buccal mucosa, lip, gingiva, tongue, floor of mouth
Atrophic glossitis	Tongue
Hemangioma	Any oral site
Plasma cell gingivitis	Gingiva
Blue, brown, black or pigmented lesions	
Ethnic pigmentation	Gingiva, palate
Varices	Floor of mouth, tongue, lips, buccal mucosa
Petechiae or ecchymosis	Any oral site
Amalgam tattoo	Gingiva, buccal mucosa
Mucocele or mucous retention cyst	Lower lip, buccal mucosa, ventral tongue, floor of mouth
Eruption cyst	Gingiva
Hairy tongue	Dorsal tongue
Hemangioma	Any oral site
Ranula	Floor of mouth
Melanotic macule	Lower lip
Smoker's melanosis	Gingiva
Melanocytic nevus	Any oral site
Blue nevus	Palate, any oral site
Malignant melanoma	Palate, gingiva

Table 30.3 Working differential diagnosis of oral lesions by location within the oral cavity and neck. The lesions are listed in order of frequency.

Ulcers of the tongue	Hodgkin's lymphoma Teratoma
Squamous cell carcinoma Traumatic ulcer Tuberculosis Primary syphilis Deep fungal infections	Congenital/developmental Thyroglossal duct cyst Dermoid cyst Epidermoid cyst Plunging ranula Laryngocele
Painful oral ulcer	Inflammatory Bacterial adenitis Viral adenitis Cat scratch disease (<i>Bartonella henselae</i>) Tuberculosis (scrofula)
Palatal mass	Mass in posterior neck
Pleomorphic adenoma Mucoepidermoid carcinoma Polymorphous low-grade adenocarcinoma Neurofibroma Schwannoma Non-Hodgkin's lymphoma Kaposi's sarcoma	Neoplastic Metastatic cancer – Posterior: nasopharynx and scalp primaries – Supraclavicular: gastric, pancreatic, lung primaries Non-Hodgkin's lymphoma Hodgkin's lymphoma Thyroid cancer
Parotid mass	Congenital/developmental Lymphangioma
Pleomorphic adenoma Warthin's tumor Mucoepidermoid carcinoma Adenoid cystic carcinoma Lymphoma Lipoma Mumps Bacterial parotitis Viral parotitis	Inflammatory Bacterial adenitis Viral adenitis Sialadenitis Cat-scratch disease (<i>Bartonella henselae</i>) Scrofula (tuberculosis)
Mass in lateral neck	Lips
Neoplastic Metastatic cancer – Upper jugular and jugulodigastric: oral cavity, oropharynx and laryngeal primaries – Lower jugular: hypopharynx and thyroid primaries – Submandibular gland: oral cavity, nasal, paranasal sinuses, and facial skin primaries Carotid body tumor Non-Hodgkin's lymphoma Hodgkin's lymphoma Hemangioma Schwannoma Salivary gland neoplasm	Dry vermillion Actinic changes Squamous cell carcinoma Keratoacanthoma
Congenital/developmental Branchial cleft cyst Thymic cyst Laryngocele Lymphangioma Hemangioma Congenital muscular torticollis Sialadenopathy	Wet mucosal surface Squamous cell carcinoma Minor salivary gland tumors
Inflammatory Bacterial adenitis Viral adenitis Sialadenitis Cat-scratch disease (<i>Bartonella henselae</i>) Scrofula (tuberculosis)	Buccal mucosa
Mass in the midline and anterior neck	Squamous cell carcinoma Minor salivary gland tumors Hyperkeratosis Lichen planus Proliferative verrucous leukoplakia
Neoplastic Thyroid cancer Benign thyroid neoplasm Non-Hodgkin's lymphoma	Floor of mouth
	Squamous cell carcinoma Sublingual gland tumors
	Hard palate in the area of the greater palatine foramen
	Mucoepidermoid carcinoma Adenoid cystic carcinoma Pleomorphic adenoma
	Retromolar trigone
	Squamous cell carcinoma Mucoepidermoid carcinoma Adenoid cystic carcinoma
	Soft palate
	Squamous cell carcinoma Dysplasia Squamous papilloma Minor salivary gland tumors

his study, who had been diagnosed with oral cancer, also had biopsy-proven dysplasia or cancer in the same anatomic location on the contralateral side, despite having normal appearing mucosa.¹² Thus, conventional oral examinations may lead to an increased amount of negative biopsies and miss some potentially malignant lesions.

Despite this, it is the authors' opinion that the advantages of routinely performing head and neck examinations on every patient at every visit greatly outweigh the drawbacks. It can be effortlessly and quickly performed, and has been demonstrated to be cost effective.^{13,14} Although it may detect many lesions that are benign, this low positive predictive value is acceptable given the minimal cost and morbidity of tissue biopsy in the oral cavity. In recent years, dental organizations have actively promoted the use of head and neck exams in oral cancer screening. Anecdotally, this has had a significant effect on the senior author's clinical practice. The majority of patients referred to the Department of Oral and Maxillofacial Surgery at the University of California, San Francisco diagnosed with oral cancer have been from providers within the dental community. Perhaps as a result of this, the authors have observed that patients present to their clinic at much earlier stages than reported in the literature. Holmes *et al.*¹⁵ and Bae and Hirsch¹⁶ have echoed this experience.

Imaging studies

Once the initial history and physical exam are completed, the next step in the clinical evaluation is often the ordering of imaging studies. There are a number of modalities available to the oral and maxillofacial surgeon, each with their own strengths, limitations, and varying degrees of invasiveness. This section aims to briefly highlight some of the advantages and disadvantages of each of these tools. As with any study, it is important for the surgeon requesting the imaging to have specific questions to be answered. When requesting imaging, the surgeon aims to: (1) better characterize the location, composition, and behavior of the lesion to assist in a diagnosis; (2) delineate the full extent of the lesion and its proximity to adjacent vital structures to aid in prognosticating as well as treatment planning; and (3) in the case of malignant disease, determine whether there is metastatic spread to the neck lymphatics.

Plain radiographs

Plain radiographs are two-dimensional images created by projecting X-rays through a patient on to a film or digital sensor. These include cephalometric radiographs, chest radiographs, dental panoramic tomograms, and dental radiographs. In general, there is very little utility in the use of cephalometric radiographs to evaluate oral and maxillofacial pathology. Tumors are usually quite extensive before they are

visible on cephalometric films. Furthermore, the anatomic extent and tumor composition are better visualized using other imaging techniques. Soft tissues are poorly imaged with these studies. Cephalometric films are not useful for detecting nodal metastasis. However, they still may be of some use when planning reconstruction, for presurgical preparation of rigid fixation plates, and for postoperative evaluation of hard tissue reconstruction.

A chest radiograph to screen for metastasis or synchronous lung primaries is part of the standard comprehensive evaluation of a patient diagnosed with head and neck cancer. Many of the risk factors that predispose a patient to developing oral cancer are also risk factors for other pathology. As many as 10% of oral cancer patients have chest metastases and 5% of patients have synchronous lung carcinomas that are detected on chest imaging.¹⁷

Dental radiographs, such as periapical, bitewing, and occlusal films, are sometimes helpful in the evaluation of lesions of the dentate segments of the mandible and maxilla. Although limited by the size of the area being visualized, the resolution of the images is far greater than other modalities. Dental radiographs are particularly useful in evaluating smaller odontogenic lesions as they can better show key features that help distinguish different odontogenic tumors or cysts from each other. These details include association with teeth, cortication, and presence of calcifications within the lesion. Furthermore, using Clark's rule (SLOB: same – lingual, opposite – buccal) is a quick and inexpensive way to determine a lesion's location in a buccal–lingual dimension.

The dental panoramic tomogram (orthopantomogram or Panorex) is a film that is commonly used by dentists and oral and maxillofacial surgeons. Much like other dental radiographs, it is quick and inexpensive. It also has the advantage of being able to effectively image the maxilla and mandible. For these reasons, it is routinely part of the initial assessment of a patient presenting with pathology of the oral and maxillofacial region, and can be very helpful in diagnosing tumors and cysts of the jaws. They may or may not be associated with teeth. The location of the lesion also helps narrow the differential. Any lesion that is located inferior to the inferior alveolar nerve canal is almost certainly not odontogenic in origin. The panoramic tomogram can also be used to look for erosion of bone by malignant soft tissue tumors, although its sensitivity for this is less than that of computed tomography (CT) or magnetic resonance imaging (MRI). It is particularly useful in treatment planning for lesions of the mandible.

Computed tomography

In 1972, Godfrey Hounsfield invented CT, a giant step forward in imaging diagnosis. By using computers to mathematically assemble multiple X-ray projections, CT is able to create cross-sectional images of the

human body. CT, therefore, has the great advantage of being able to eliminate the obscuring of deep structures by superficial structures. It allows the surgeon to appreciate a tumor's location and size in three dimensions, thus accurately defining a tumor's relationship to important vital structures, such as the great vessels, skull base, and orbit. In addition, CT is far superior in appreciating differences in soft tissue planes and vasculature. Fat, muscle, and water can be differentiated fairly easily. This ability is further enhanced by contrast. This has also allowed surgeons to screen for nodal metastasis with reasonable sensitivity.

There are a few disadvantages associated with the use of CT. Although the cost of a CT scan is decreasing as accessibility increases, the study still remains expensive. The effective dose of radiation from a head and neck CT is relatively small when compared to annual exposure to natural radiation. But, at around 1000–4000 μSv , it is not insignificant.^{18,19} Furthermore, this is still a greater effective dose than that of plain radiography, and may be of concern to some patients, especially when serial CT scans are required. Another drawback of the use of CT in the maxillofacial region is the obscuring of the image from artifacts arising from high-density materials such as dental filling or surgical hardware. Oral cancer most commonly affects older patients, who are more likely to have dental restorations that make CT imaging difficult.

Since 1972, several advances in CT technology have been introduced that have made CT faster, yield images with improved resolution, and have made it more accessible. Recently, the cone-beam CT is an iteration of the technology that has been increasingly adopted for use in the oral and maxillofacial region, in particular for use in prosthodontic and orthodontic treatment planning, but also for use in diagnosing pathology as well as surgical and radiotherapy treatment planning.^{20,21} Cone-beam CT uses an X-ray beam in the shape of a cone that rotates and scans the entire volume of interest, as opposed to a conventional fan-beam CT, which uses a fan-shaped X-ray that rotates around and advances along the volume of interest. Because of this, cone-beam CT decreases the effective dose to roughly around 23–52 μSv .^{22,23} In addition, cone-beam CT is less susceptible to dental artifacts. The spatial accuracy is comparable to conventional CT, with its relative geometric error measured in tenths of a millimeter.²⁴ However, some of the drawbacks of the cone-beam CT are its inferior soft tissue visualization, which limits its use in diagnostics for oral and maxillofacial pathology and staging of the neck, and that it is limited in the total volume that can be visualized with a single scan.

Another recent advance in surgical planning has been the use of conventional CT to create stereolithic models and customized surgical reconstruction plates. The authors have used these custom tools to simplify and expedite the surgical reconstruction,

especially when reconstructing mandibular defects. Although custom reconstruction plates certainly make the surgeon's work easier, they are an additional expense and whether they result in a clinically significant improvement in the surgical outcome remains to be studied.

Magnetic resonance imaging

MRI is a technology that is based upon the science of nuclear magnetic resonance. In simple terms, the system works by placing a patient in a magnetic field that aligns the protons of hydrogen atoms (most commonly found in water) in the direction of the field. A second magnetic field is then momentarily introduced that causes protons to be deflected from this axis and, in the process, absorb some of its energy. Once this second field is released, the protons that were previously deflected return to the initial axis of the first magnetic field and release the absorbed energy as a radiofrequency. The radiofrequencies are then detected by the MRI scanner and are used to determine the position of the respective protons. Several of these additional fields are used along the volume of interest and the information is compiled into a three-dimensional image that can be viewed in sections. Gadolinium, a paramagnetic material, is used to enhance areas of inflammation or increased vascularity.

As with CT, the MRI creates spatial imaging that allows the surgeon to visualize a tumor in three dimensions and appreciate the tumor's relationship to adjacent structures. In addition, MRI has several advantages over CT. It has superior soft tissue resolution, and, as such, is the preferred imaging of choice of neurologic pathology. It is minimally affected by artifacts from high-density materials. MRI also does not use ionizing radiation and is considered non-invasive. In addition, the use of certain protocols, namely magnetic resonance angiography (MRA), allows for the imaging and detection of blood flow, which is useful in the preoperative assessment of vessels for microvascular reconstruction.

As the technology uses a strong magnetic field, implanted paramagnetic materials, such as pacemakers, cochlear implants, deep brain stimulators, or older vascular aneurysm clips, are an absolute contraindication for MRI. These can cause motion and thermal injury to surrounding tissues. MRI scanners are much slower than CT scanners, with scanning times up to 40 minutes on older machines. Because of this, motion artifacts are a problem and patients who are unable to lie still (such as children) may require anesthesia to have an MRI. Furthermore, patients who suffer from claustrophobia may also find undergoing an MRI difficult.

MRI is the anatomic imaging study that is preferred by the authors for evaluating patients with oral cancer. It has superior soft tissue imaging when compared to CT, which is helpful for determining extent

of soft tissue invasion as well as nodal metastasis, and is not plagued by dental artifacts.

Positron emission tomography and PET/CT

Positron emission tomography (PET) is an imaging modality that highlights areas of the body with increased metabolic activity. Radionuclides are bound to molecules that are important to human metabolism. The most common tracer used in PET is ^{18}F -fluoro-2-deoxy-D-glucose (FDG), which is a radioactively labeled glucose. FDG is administered intravenously and becomes sequestered in cells that are actively taking up glucose. Malignant cells that are more mitotically and metabolically active would then have relatively greater uptake than surrounding non-malignant cells. Once sequestered in cells, the FDG undergoes radioactive decay to a more stable molecule, emitting positrons in the process. These positrons combine with electrons within the adjacent tissues and annihilate, resulting in a release of gamma rays 180 degrees from each other. These gamma rays are then picked up by detectors within the PET scanner and triangulated to determine the anatomic location of the metabolically active tissue.

PET is effectively used in the detection of distant metastases in cancers for which metastasis is common, such as cancers of the lung and colon. In addition, PET scans may be used to evaluate the patient with nodal metastasis and an unknown primary. The detection rates for unknown primaries are greater than MRI or CT, at 29% compared to 15–20%.^{25–27} However, these rates are still relatively low. On occasion, PET may also detect synchronous primaries in other locations.

One of the limitations of PET is the lack of anatomic detail displayed by the images. In order to remedy this, computer software registration has been developed to combine the biochemical imaging of PET with the anatomic detail afforded by CT. The combination of these two modalities is called PET/CT. Initially, this technique was quite labor-intensive, as technicians would have to manually combine images from different scanners taken at different time points. However, integrated PET/CT scanners have simplified the task of obtaining these composite images and have improved consistency and reliability of producing quality images.

The use of PET/CT for evaluation of lymph node metastases and recurrence of tumors is well established.²⁸ In addition, it has been studied for use in evaluating the clinically node negative neck. PET/CT is superior to CT or MRI for detecting occult lymph node metastases, although the difference may not be clinically significant.^{29–31} Nahmias *et al.* found that the use of PET/CT did not change the decision to perform an elective neck dissection in the patients studied.³⁰ Because of this, it is generally not recommended as part of the initial workup of head and neck cancer.

For head and neck cancer, the indications for PET are: (1) part of the assessment for recurrence in symptomatic patients or in patients with suspicious but non-specific findings on MRI or CT; (2) part of the assessment of a patient with an unknown primary; and (3) staging for patients with advanced cancers. In the senior author's practice, PET scans are not routinely used in the initial workup of a patient with oral and maxillofacial pathology.

Ultrasound

Ultrasound images are created from the recording of the amplitudes of reflected high-frequency sound waves. The primary advantage of this tool is that anatomy can be visualized dynamically in real time by the sonographer. Other advantages are that ultrasound is extremely safe and relatively inexpensive.

By varying the frequency of ultrasound used, the sonographer can also image objects of varying depths. Higher frequency ranges, 5–10 MHz, are used in the head and neck to visualize more superficial soft tissue structures. Calcifications are also well imaged by ultrasound, which is useful in diagnosing sialoliths, phleboliths, and atherosclerosis. However, tissues containing air and bone reflect nearly all ultrasounds. Thus anatomy deep to bony structures, such as the angle of the mandible, or posterior to air-filled objects, such as the trachea, are not well visualized. In addition to the standard gray-scale ultrasound images obtained, Doppler ultrasound records shifts in reflected frequencies to image moving objects. Clinically, this allows for the imaging of blood flow.

Ultrasound has several indications. It is useful in evaluating superficial nodules of the neck, salivary glands, and thyroid gland. Ultrasound is very effective in identifying cystic lesions, which appear as well defined hypoechoic (dark) masses. Benign tumors of the salivary and thyroid glands are similarly well defined, lobular, and hypoechoic. Lesions that are less well defined are suspicious for malignancy and should prompt the clinician to order additional studies.

Ultrasound is also highly effective in the evaluation of the lymphatic system of the neck, able to determine the presence, quantity, size, shape, and internal characteristics of lymphadenopathy. Most of the lymphatic chains clinically relevant to oral cancer are superficial and are well imaged by ultrasound. One exception is the retropharyngeal lymph nodes that can be involved with cancers of the pharynx and larynx. Because ultrasound allows for dynamic imaging, it is used by cytopathologists for guiding fine-needle aspiration biopsy (FNAB) of smaller, impalpable lesions.

Some practices have adopted the use of ultrasound to serially monitor and expectantly manage patients with clinically node negative (N0) necks.³² Although one group has published on the utility of this method, other groups have not replicated their success.^{6,33}

Part of the problem is that the reliability of this technique is highly dependent on the experience and skill of the sonographer in this specific application. As such, the authors do not use ultrasound for expectant management of the N0 neck.

Considerations for radiation exposure

With the exception of ultrasound and MRI, the imaging tools mentioned above expose patients and providers to varying degrees of radiation. The estimated effective doses for common imaging studies are listed in Table 30.4. Although the dosages from dental or head and neck radiography are hundredths of lethal doses and the risk of tissue injury or carcinogenesis is exceedingly small, the risk still exists. Therefore, imaging should not be haphazardly ordered. The risk of harm to the patient should always be weighed against the potential benefit from the information collected.

However, the risk of radiation exposure is not an absolute contraindication. One scenario that is exceedingly common is the pregnant patient with oral and maxillofacial pathology. It is important to

remember that the American College of Obstetricians and Gynecologists has published guidelines for the ordering of imaging in pregnant patients.³⁴ These are listed in Tables 30.5 and 30.6.

Obtaining a tissue diagnosis

Much information can be gathered from taking the history, performing the physical exam, and acquiring the appropriate imaging studies. However, histologic analysis is absolutely essential for a definitive diagnosis of oral pathology. For suspicious lesions of the soft or hard tissues of the oral cavity, a tissue biopsy is the sole method to obtain this.

There is often reluctance, mostly on the part of the practitioner, to perform biopsies. Deferring a biopsy is a reasonable approach if the clinical features of the lesion are consistent with a process that is entirely benign and is not treated by excision. However, if the lesion does not respond to the appropriate intervention for the initial diagnosis, a biopsy is absolutely indicated. Therefore, it is critical for the surgeon, if the plan is to treat empirically, that the patient be closely observed and followed. It is also crucial for the surgeon to be able to formulate a working differential diagnosis, in order to guide the decision of whether to perform a biopsy or not. Failure to perform a biopsy or make a referral for a biopsy due to a clinician's lack of experience with treating oral lesions is inexcusable. If a malignant disease or disease that is treated by wide excision is on the differential diagno-

Table 30.5 American College of Obstetrics and Gynecology guidelines^a on the diagnostic imaging in the pregnant patient.

1. Women should be counseled that X-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rad has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic X-ray procedures from being performed on a pregnant woman. During pregnancy, other imaging procedures not associated with ionizing radiation (e.g. ultrasonography, MRI) should be considered instead of X-rays when appropriate.
3. Ultrasonography and MRI are not associated with known adverse fetal effects.
4. Consultation with an expert in dosimetry calculation may be helpful in calculating estimated fetal dose when multiple diagnostic X-rays are performed on a pregnant patient.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.
6. Radiopaque and paramagnetic contrast agents are unlikely to cause harm and may be of diagnostic benefit, but these agents should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

sis, than a biopsy should be performed. Or, if the initial impression consists of a disease whose treatment is morbid, such as long-term corticosteroid use for autoimmune disease, than a biopsy is necessary to confirm that diagnosis.

Once the decision is made to perform a biopsy, the surgeon must determine: (1) whether the biopsy should be excisional or incisional; (2) what is the setting that the biopsy should be performed under; (3) what type of instrumentation should be used; and (4) decide where the biopsy specimen should be taken from.

Excisional and incisional biopsy

For an excisional biopsy, the entire lesion is removed. This approach is indicated if the suspicious lesion is likely to be benign, likely to be cured by local excision, and small enough that local excision is feasible. For an incisional biopsy, only a sample of representative tissue is taken from the patient, leaving the rest of the lesion *in situ*. This is indicated if the lesion is suspicious for malignancy or the area involved is larger than can be excised.

Deciding between an excisional biopsy and an incisional biopsy should be relatively simple. If a surgeon is seriously considering a malignant lesion as part of the differential diagnosis, even if it is not the most likely diagnosis, an incisional biopsy should be performed. If the surgeon is only considering benign diseases on the differential diagnosis and the lesion is localized, an excisional biopsy should be performed.

However, it is important to remember that the primary advantage of performing an excisional biopsy over an incisional biopsy is that, with excisional biopsies, benign lesions can be both diagnosed and treated with a single procedure. Unfortunately, the drawback of performing excisional biopsies is

quite significant. If the surgeon mistakenly excises an oral lesion that is malignant, that surgeon has obscured the margins of resection for the definitive treatment. Unless the oncologic surgeon is the same surgeon performing the biopsy, it will be difficult for the oncologic surgeon to appreciate the original size and extent of the lesion. The ultimate consequence of excision of a malignant lesion is that the ability to adequately perform an oncologic resection is greatly compromised. Thus, it is safer to perform an incisional biopsy if one is uncertain.

Setting for performing the biopsy

Asking the pathologist for a histologic diagnosis is the same as asking any other specialist for a consultation. The request needs to be a specific question framed in an accurate and thorough clinical picture. The first half of the required information is the history, clinical exam, and the surgeon's impression. The second half is providing the pathologist with an adequate specimen to analyze and perform the necessary tests. In other words, it is critical for the surgeon to work very closely with the pathologist to maximize the team's ability to come to an accurate diagnosis.

An often overlooked step in ensuring an adequate biopsy is choosing the appropriate setting for performing the biopsy. Many lesions are amenable to biopsy in the clinic. These include lesions of the skin, lesions of the lip, and mucosal lesions of the oral cavity. However, large lesions of the oral cavity that extend into the oropharynx or oral lesions with an intraosseous component may be more efficiently sampled in the operating room under general anesthesia. Having the patient under general anesthesia affords the surgeon the opportunity to take the time to adequately expose and visualize the lesion and sample enough tissue in enough locations, without being limited by concern for keeping an awake patient comfortable. In addition, if the plan is to perform an excisional biopsy, frozen section analysis of incisional biopsy specimens can be performed initially to verify that a lesion is, in fact, benign and not in need of an oncologic resection.

Too frequently, the desire to minimize the morbidity from a large biopsy or to avoid the hassles of scheduling time in the operating room compromises the adequacy of the biopsy specimen. If the surgeon does not feel confident that the lesion can be comfortably and thoroughly sampled in the clinic, there should be no hesitation to do so under general anesthesia. A misdiagnosis or delay in diagnosis is much more troublesome than the short postanesthesia recovery period from a proper biopsy.

Instrumentation for performing the biopsy

A biopsy should be done with a sharp cutting instrument. A scalpel, fine scissors, a biopsy punch, or a combination of these can be used. The authors feel

that electrocautery or lasers do not have a place in the biopsy armamentarium. The use of electrocautery will destroy the tissue structure along the edges of the biopsy specimen. This not only reduces the available tissue for analysis, but it may obscure important prognostic markers such as margin status and depth of invasion. The use of a laser for vaporization does not leave any specimen for pathologic analysis.

The punch biopsy is particularly useful in sampling friable lesions. In these lesions, it may be difficult to adequately grab the tissue, as it often crumbles under the pressure of the tissue forceps. A punch can be used to cut a cylindrical piece with downward pressure, and in the same motion can be scooped out to cut the base and deliver the specimen. In addition, by driving the biopsy punch to the hub of the cutting blade, it is quite simple to obtain a specimen of an adequate depth.

Deciding where to sample with the biopsy

When performing an incisional biopsy, much depends on selecting a representative sample of the lesion to be diagnosed. The portion of the lesion that yields the most information will vary depending on the nature of the lesion and what is suspected to be the most likely diagnosis.

Local anesthesia should involve nerve blocks and local infiltration around the lesion of interest. Take care not to administer anesthetic directly into the lesion itself so as to not distort the tissue architecture.

In ulcerative lesions that are suspicious for malignancy, the biopsy should be performed on the ulcer itself, near the edge of the ulcer. Normal mucosa does not need to be removed, as it does not provide any meaningful information. The tissue near the edge of the ulcer will give a cellular picture that is least clouded by tissue necrosis or inflammation. The biopsy should have a minimum depth of 5 mm to enable the pathologist to view the depth of invasion. Ulcers that are suspicious for an infectious process are performed in the same way.

If the ulcerative lesion more closely fits an autoimmune process, a biopsy of the normal tissue should be performed. In vesiculobullous diseases, such as pemphigus vulgaris or erythema multiforme, the tissue from the ulcer itself does not provide helpful information, as it is the epithelium that is affected and ulcers are denuded of epithelium. Furthermore, the ulcer may be colonized by oral flora that can cloud the histologic picture. The surgeon should take more than one biopsy specimen so that one can be processed and stained with the standard hematoxylin and eosin stains and the other can be processed for direct immunofluorescence.

Biopsies in the oral cavity do not necessarily require closure, particularly if it is an incisional biopsy. However, if the surgeon is performing an excisional biopsy, and the incisions and tissues facilitate this, closure can help with hemostasis, comfort, and

improved healing. Biopsies of the lip are amenable to this and can be facilitated if the incisions are made vertically in the shape of an ellipse. When closing larger tongue excisions, the surgeon should take care to not tether the tongue to the floor of mouth. It may be better to allow the tongue to heal by secondary intention or to close the wound with a skin graft.

The differential diagnosis for intraosseous lesions includes odontogenic cysts or tumors, non-odontogenic cysts or tumors, fibro-osseous diseases, epithelial neoplasms that have eroded bone, vascular lesions, infectious processes, and metastatic diseases. Before an intraosseous lesion is accessed, it is advisable to rule out a vascular lesion, as cutting into a high-flow vascular malformation could lead to catastrophic hemorrhaging. Exam findings, such as a pulsatile lesion, audible bruits, or palpable thrills would be suggestive of a vascular lesion. Often there are associated soft tissue changes. The overlying mucosa may appear expansile and blue in color. In high-flow lesions affecting the dentoalveolar segments, there is frequently gingival hypertrophy with bleeding from the gingiva sulci. The increased vascular flow may also cause ipsilateral maxillary or mandibular hypertrophy. A Doppler examination may also be helpful in making this determination. If the lesion is likely a vascular malformation, then the lesion should be embolized by interventional radiology before surgical excision. Regardless, it is recommended that intraosseous lesions that cannot be ruled out as vascular be aspirated before they are entered. If blood is aspirated, the syringe should be removed from the needle. Pulsatile flow from the hub of the needle is consistent with a high-flow vascular malformation. In this situation, the needle should be withdrawn and pressure should be applied to achieve hemostasis. Blood that is not pulsatile and stops quickly, or aspirate that is non-bloody are signs of a lesion other than a vascular lesion.

Basic surgical principles apply when accessing the lesion of interest. When planning the incision, the design should allow for a closure that lies over solid bone and not a cavity. The length of the incision should allow for adequate retraction to fully visualize the extent of the lesion. If necessary, incorporate releasing incisions. If the lesion involves the mucosa, the affected mucosa should be sampled along with the bony lesion.

Once the area involved is visualized, a window in the bone may be created if the lesion has not already perforated the bone cortex. This will allow the lesion to be seen grossly. If the lesion is cystic, take note of the nature of the cystic contents, documenting the consistency, color, and whether it is characteristic for certain pathology. Generously sample the cyst lining. If the lesion is solid or solid with cystic components, sample tissue from the most central part of the lesion.

At the University of California, San Francisco, it is a common practice, if the lesion is obviously cystic, to marsupialize the cyst and place a drain that starts

within the deepest portion of the cystic space and exits through the soft tissue flap into the oral cavity. In this way, if the lesion ultimately is diagnosed as either a keratocystic odontogenic tumor (formerly known as odontogenic keratocyst) or a dentigerous cyst, it has also been simultaneously treated.

When an excisional biopsy or resection is performed, the specimen must be properly oriented with sutures. Two sutures in different dimensions, along with a proper description including location and laterality, allow the pathologist to orient the specimen. The surgeon's description should also include the lesion characteristics, such as condition of the overlying mucosa, texture, size, consistency and infiltration. For osseous lesions include a radiograph. If the margins are positive for atypical cells then proper orientation and a detailed description allow the surgeon to accurately perform definitive surgical excision.

Fine-needle aspiration biopsy

Fine-needle aspiration biopsy (FNAB) is a technique in which a fine needle is passed into a mass, cells are aspirated, and these cells are then prepared on slides and analyzed by a cytopathologist. The use of aspiration biopsy has been practiced for well over a century. Initially, the technique involved the use of a large-bore needle under local anesthesia, but it has since evolved to be used with fine-gauge needles. At most institutions, this is performed by specialized cytopathologists. Having a physician experienced in performing this procedure and diagnosing diseases of the head and neck is essential, as it can be difficult to obtain an adequate sample and make the correct diagnosis based upon cytology.

Indications

FNAB can be used as the method for initial diagnosis for almost any mass in the head and neck region, particularly in disease processes that are not clearly infectious. The differential diagnoses for neck masses are outlined in Tables 30.3 and 30.7. This technique is

helpful in distinguishing neoplastic processes from those that are inflammatory or reactive. However, the most common indication for the use of FNAB is a mass located in the neck, thyroid gland, or salivary glands. Fig. 30.3 shows an algorithm for the evaluation of a patient with a neck mass.

There are no absolute contraindications to FNAB. Relative contraindications include any medical comorbidities that would preclude any minor surgical procedure, in particular significant coagulopathies or thrombocytopenia. In addition, lesions that are suspicious for high-flow vascular malformations should not be subjected to FNAB. Masses overlying or underneath important anatomic structures, such as carotid body tumors, may be difficult to sample. In the past, there has been concern over tumor seeding along the track of the fine needle. However, tumor seeding has not been a problem with this procedure.³⁵

Technique

The procedure should begin by proper positioning of the patient. This may require the use of a shoulder roll to assist in extension of the neck or rotating the head of the patient to expose the side of interest. The area to be biopsied should be then cleaned with an alcohol swab. The area to be biopsied can be anesthetized with local anesthetic, however this is usually not necessary as the anesthetic needle is the same gauge as the biopsy needle. Have an empty syringe ready with a 23–27 gauge needle attached. The plunger should be drawn back to allow 1 ml of air in the syringe.

The mass is then palpated and stabilized with the non-dominant hand. The needle is then introduced into the mass. The patient should be instructed to not move or swallow while the needle is inserted. The plunger is pulled back from the syringe to create a vacuum. The needle should be deliberately pushed in and out of the mass with short 2–3 mm vibratory strokes. If the mass is cystic, the fluid should be allowed to drain first. To do this, first insert the needle with the syringe with the plunger removed. After draining, the needle can be used to sample any remaining solid material or the cyst lining. Once the biopsy specimen has entered the needle, the needle can be withdrawn. This process should be repeated a minimum of four times.

The aspirate is then deposited on to two separate slides. One slide should be air dried while the other slide is fixed. The second slide can be wet-fixed with 95% ethanol or spray-fixed. The needle is then rinsed with balanced salt solution.

If the person performing the FNAB is not the cytopathologist that will be reviewing the specimen, then it is critical that adequate documentation is sent with the biopsy. As mentioned above, the documentation should include the patient's information, relevant history, description of clinical findings, description of

the biopsy procedure, and the surgeon's clinical impressions. The description of the biopsy procedure should include the number of needle passes, consistency of the mass being biopsied, volume of fluid aspirated, and the characteristics of the aspirate.

Lymph nodes

Lymphadenopathy is a common presentation of disease among patients with head and neck pathology. As discussed above, the differential diagnosis

includes metastatic diseases, reactive lymphadenopathy, lymphoma, and inflammatory processes, both infectious and non-infectious. In patients older than 40 years of age, lymphadenopathy should be considered malignancy until proven otherwise. Features that are suggestive of malignancy include a chronic history, unexplained etiology, lymphadenopathy that is fixed to overlying or underlying tissues, induration, and lack of findings more consistent with inflammatory processes, such as redness, fluctuance, warmth, or purulent drainage. The presence or his-

tory of head and neck malignancy is highly concerning for metastatic or recurrent disease.

FNAB is the part of the initial diagnostic workup of lymphadenopathy. One of the primary indications for performing FNAB is to decipher the presence of metastatic disease or lymphoma. Several studies have demonstrated that FNAB can determine a specific diagnosis for lymphadenopathy 82–96% of the time.^{36–38} FNAB is especially useful for distinguishing cystic lesions from inflammatory lesions and benign lesions from malignant lesions. In this way, FNAB can be a cost-effective, minimally invasive means for evaluating neck masses in patients for whom the provider has a low index of suspicion for malignancy.

FNAB is particularly useful in diagnosis of metastatic disease or recurrent lymphoma. However, the utility for FNAB in the initial diagnosis of lymphoma is controversial. The use of several analytical techniques such as flow cytometry to detect specific cell surface antigens, immunophenotyping of immunoglobulins, and cytogenetics to detect specific chromosomal rearrangements can increase the diagnostic power of this technique.^{39–41} Despite this, if non-Hodgkin's lymphoma is suspected, an open biopsy remains the definitive diagnostic modality as it provides more ample tissue to perform the above studies.

If the lymphadenopathy is suggestive of infectious processes, the aspirate should be sent for microbiologic testing. Bacterial, mycobacterial, fungal, and viral organisms can all manifest as lymphadenopathy.

On occasion, metastatic disease can manifest as lymphadenopathy in the absence of an obvious primary tumor. The diagnosis of neck disease with an unknown primary should be followed with anatomic imaging and panendoscopy with biopsies.

A negative result from FNAB of lymphadenopathy, like all diagnostic tests, should be interpreted in context of the clinical picture. If the history or exam is at all concerning and the clinical suspicion for malignancy remains high, the surgeon should push the diagnostic evaluation further, including repeat FNAB, panendoscopy, and open excisional biopsy of the lymphadenopathy.

Salivary glands

FNAB is part of the initial evaluation of swellings of the major salivary glands that cannot be ruled out as neoplastic in etiology. The benefit of using FNAB in diagnosis of salivary gland masses is that the thin caliber of the needle avoids injury to critical related structures, namely the facial nerve that is intimately associated with the parotid gland. FNAB is able to effectively distinguish between salivary gland neoplasms, soft tissue neoplasms, parotid lymph nodes, lymphoepithelial cysts, and sialadenitis with good sensitivity and specificity, 90% and 80% respective-

ly.^{42,43} More importantly, it is helpful in distinguishing benign lesions from malignant salivary gland neoplasm and lymphomas, a distinction that would alter treatment.

Like all of pathology, the quality of results depends a great deal on the experience and skill of the cytopathologist. The differential diagnosis for salivary gland masses, as already mentioned, is quite broad. In addition to the potential diagnoses already mentioned, diseases of adjacent tissues may mimic an intraparotid lesion. Secondary alterations of tissues surrounding a disease process, such as chronic inflammation, cystic changes, clear cell changes, sebaceous differentiation, mucin production, and oncocytic changes can further confuse the picture. Finally, because FNAB samples cells rather than tissues, diagnoses may be extremely difficult to distinguish from each other. For example, a pleomorphic adenoma may manifest with plasmacytoid and lymphocyte-like myoepithelial cells, a finding that can easily be confused for a plasmacytoma or malignant lymphoma.⁴⁴ As such, it is critical that the surgeon is able to communicate well with the pathologist and be able to interpret the pathology report to make certain that it is consistent with the rest of the patient's clinical picture.

Some authors have argued that FNAB of salivary glands is an unnecessary step in the workup of parotid masses, given that the majority (80%) are benign and 80% of these masses are pleomorphic adenomas. Some surgeons argue that the majority of lesions, as well as several malignant lesions, may be diagnosed and treated simultaneously by a superficial parotidectomy. The minority of malignant neoplasms that would require more extensive treatment would be able to be distinguished by a careful history and examination.⁴⁵ Although this logic is valid, it is the practice within the authors' department to take a more cautious approach. Given that undergoing FNAB is well tolerated, fairly quick, and minimally invasive, it does not seem justified to proceed to major surgery without a tissue diagnosis. Anecdotally, there have been a small number of patients in the senior author's practice whose examinations were deceiving, and ultimately benefited from having a tissue diagnosis prior to surgery.

Thyroid nodules

In the management of thyroid nodules, FNAB has been shown to be a highly accurate and useful tool, decreasing the number of unnecessary surgeries and increasing the rate of diagnosis of thyroid malignancies in several studies.⁴⁶ It has been recommended as part of the initial workup of a thyroid nodule.^{47,48} The indications for FNAB of the thyroid are: (1) a solitary thyroid nodule; (2) a multinodular goiter with a growing nodule; and (3) new nodules in patients with Hashimoto's thyroiditis.³⁵ Once performed, the cytopathologist will typically report the findings as

unsatisfactory, benign, indeterminate, suspicious, or malignant. The findings for these reports are 17% for unsatisfactory, 69% for benign, 10% for indeterminate or suspicious, and 4% for malignant.⁴⁷ FNAB is limited in its ability to distinguish follicular adenomas and Hurthle cell adenomas from their malignant counterparts, as this distinction can only be made by identifying invasion in a tissue sample. Otherwise, the sensitivity and specificity for diagnosing thyroid malignancy has been reported as 83% and 92% respectively. False-negatives can occur 1–5% of the time and are commonly associated with aspiration of cysts greater than 3 cm or nodules less than 1 cm.^{35,49} False-positives can occur around 1% of the time, usually associated with inflammatory thyroid diseases, such as Grave's disease or Hashimoto's thyroiditis, or a toxic thyroid nodule.

A FNAB that is reported as unsatisfactory should be repeated. Similarly, indeterminate biopsies should also be either repeated or followed with a more definitive biopsy, as 25% of these are malignant.⁴⁷ Benign nodules can be excised, followed expectantly, or treated medically if appropriate. Only 1% of benign nodules are ultimately cancer. Suspicious nodules should undergo further workup, as 20% of these are cancer.³⁵ The workup can include additional imaging, such as a radionuclide scan, or excisional biopsy. Radionuclide scans that are cold should be diagnosed surgically. However, given that the majority of nodules are cold, the utility of the scan might be questioned. Malignant lesions should be treated with oncologic resection, with chemotherapy and radiation therapy as dictated by the specific diagnosis.

Limitations

In addition to the indications mentioned above, some institutions have published reports of the use of FNAB to diagnose benign intraosseous pathology of the maxilla and mandible. Specifically, FNAB has been used by some to definitively diagnose odontogenic tumors such as ameloblastoma.^{50,51} Generally speaking, the primary question that FNAB intends to answer is whether a lesion is likely to be malignant or benign. In some instances, the cytologist may be able to determine the predominant cell type of the aspirate. However, definitive diagnoses of odontogenic tumors of the neck require tissue that can only be obtained by surgical biopsies. Having a definitive diagnosis is critical as the surgical treatment can vary from a simple enucleation to wide resection. Unfortunately, only a paucity of case reports support the use of FNAB for diagnosis of odontogenic tumors. Therefore, the authors do not recommend the use of FNAB for this indication.

Open biopsy for lymphadenopathy

An open lymph node biopsy is indicated when FNAB is suggestive of lymphoma, has ruled out metastatic

disease, or is inconclusive after multiple attempts. Proper diagnosis of lymphoma requires sampling of tissue, as mentioned above. In the case of non-specific or inconclusive findings, obtaining adequate tissue facilitates the pathologist's ability to reach the correct diagnosis.

It is important to remember that open biopsy for lymphadenopathy should not be part of the initial evaluation of the neck swelling. Inadvertent violation of fascial planes by open biopsy of a metastatic node risks seeding of malignant cells throughout the neck and has been demonstrated to significantly increase disease-related mortality.⁵² Although some recent studies have challenged this dogma, suggesting that inappropriate open biopsy may not be as poor a prognosticator if followed by a radical neck dissection and radiation therapy, it is generally regarded to be below the standard of care to proceed to open biopsy without first obtaining an FNAB.^{53,54}

When performing an open biopsy for lymphadenopathy, the surgeon should approach the surgery as if performing a neck dissection by maintaining fascial planes and removing the fibroadipose-lymphatic tissue in continuity. Once removed, the surgeon should have the pathologist examine frozen sections to confirm that the diagnosis is not metastatic head and neck cancer. The surgeon should be prepared to perform a completion neck dissection if the frozen sections reveal that the lymphadenopathy is indeed metastatic cancer.

Once the lymph node is appropriately removed, the tissue should be submitted for testing related to the differential diagnosis. Cultures and sensitivities are sent if the disease is potentially infectious in etiology. The specimen should be sent for pathology to rule in or out metastatic disease. If the pathology is suggestive of lymphoma, additional studies will be required.

Summary of the approach to the oral and maxillofacial pathology patient

The evaluation of the oral and maxillofacial pathology patient begins with a focused history and physical examination. An experienced clinician will develop a differential diagnosis early on and will test and refine his or her hypotheses as they interview and examine the patient. Imaging studies are selected and ordered to answer specific questions and based upon specific indications, as each type of study has its strengths and weaknesses. If a neoplastic process is suspected, it should be confirmed with a tissue diagnosis. FNAB is extremely helpful as a first-line evaluation tool for neck or salivary gland masses. For most diseases, a surgical biopsy is necessary for a definitive diagnosis. If a neoplastic disease is suspected, the clinician should not hesitate to perform a biopsy or refer to an appropriate specialist. Fig. 30.4 shows a basic algorithm for evaluation of the oral and maxillofacial pathology patient.

Fig. 30.4 Algorithm for evaluation of the oral and maxillofacial pathology patient.

Adjunctive diagnostic tools

Many premalignant and malignant lesions are small and are difficult to appreciate. Even when they are visualized, providers who do not frequently deal with diagnosis of diseases of the oral and maxillofa-

cial region are, understandably, reticent to aggressively biopsy all suspicious lesions. Both of these scenarios are especially true when the lesions are relatively innocuous appearing. As a result, it is common for the generalist to dismiss more serious diseases from the differential diagnosis, such as oral

cancer, because they are rare or the patient's demographics do not necessarily fit the disease. Unfortunately, this is a fallacy, as it has been demonstrated that innocuous lesions can indeed be cancer and that there is an increasing incidence of oral cancer in younger adults who have never used tobacco or abused alcohol.⁵⁵

Therefore, the ability to perform a minimally invasive test to detect inconspicuous lesions or determine the malignant potential of borderline suspicious lesions would be a highly attractive tool. The following section will discuss the most commonly available adjunctive diagnostic tools that have been used to fill this niche, the relevant literature evaluating their utility, and the authors' opinions regarding their places in the oral and maxillofacial pathology workup.

Toluidine blue

Toluidine blue is a vital dye that stains nuclear material. As a consequence, it preferentially stains tissues with high rates of cellular turnover, namely neoplastic mucosa.

Technique

To perform the stain, have the patient first rinse his or her mouth with 1% acetic acid for 20–30 seconds. Following this, the patient should rinse with water twice, again for 20–30 seconds each time. Next, have the patient rinse with 1% toluidine blue solution. Follow this with 20–30 seconds of rinsing with 1% acetic acid and 20 seconds of rinsing with water.

Dark blue staining indicates a positive result, pictured in Fig. 30.5, which represents the dye binding to nuclear material. Pale blue staining is more representative of benign lesions, which show no nuclear stains on histology. The papillae of the dorsal tongue also tend to retain toluidine blue.

Indications

Toluidine blue has been demonstrated to be an effective adjunctive screening tool in identifying premalignant lesions or oral cancer recurrences in high-risk populations, particularly those who have already been diagnosed with having oral dysplasia or

oral cancer. Gray *et al.* published an extensive review of the literature evaluating the use of toluidine blue as an adjunctive screening tool.⁵⁶ The 14 studies included in the review examined the use of toluidine blue in aiding specialists in detecting lesions that were not readily visible with a conventional oral examination. Overall, the sensitivity for detecting oral cancer ranged from 40–100% and the specificity from 31–92%. From this series, Barrellier *et al.* found six oral cancers that were not detected by conventional oral examination alone, supporting its use as an aid to the conventional oral examination for detecting lesions.⁵⁷ However, although highly sensitive for detecting oral cancer, it has its limitations. Warnakulasuriya and Johnson noted that 50% of oral lichen planus lesions stained positively with toluidine blue, highlighting its potential for false-positives.⁵⁸ In addition, Martin *et al.* found that only 42% of dysplasias stained positively, underscoring an important limitation in the dye's abilities in lesion detection.⁵⁹ Therefore, the surgeon must be careful not to overextend the utility of this tool. Although the tool is highly sensitive, the literature does not support the use of toluidine blue to rule out malignancy.

Recent studies have also suggested that toluidine blue might be used to predict degree of risk for transformation in oral dysplasia. Zhang *et al.* found that toluidine blue preferentially stained lesions that had high-risk histologic features. More importantly, it predicted risk of transformation in lesions with no histologic features of dysplasia and the staining was correlated with patient outcome.⁶⁰ However, the degree of staining can be subjective, and thus should not be the determining factor for not performing a biopsy.

In addition to the above indications, the use of toluidine blue has been also been suggested as a potential screening tool. Unfortunately, there is currently no evidence to support the use of toluidine blue to screen for oral cancer in the general population.

Tissue fluorescence

Autofluorescence is a property of cells whereby specific wavelengths of light are absorbed by molecules within cells, causing them to move into an excited state. As the molecules return back to their resting state, the energy from the excitation is released in the

Fig. 30.5 (a) Staining of the oral tongue by toluidine blue prior to decolorization. (b) Tongue stained with toluidine blue after decolorization. The area of dysplasia retains the vital stain and remains dark blue. Note that the filiform papilla of the dorsal tongue stains a pale blue.

form of fluorescence emissions. There are several types of molecules that exhibit autofluorescence, but most commonly exist in the mitochondria and lysosomes of the cell. Porphyrins in erythrocytes also contribute to autofluorescence.

It has been observed that cancer cells have different autofluorescence emission patterns than normal tissues.⁶¹ This has led to the development of technologies that aim to highlight the differences in autofluorescence in order to aid in detection of pathologic oral lesions.^{62–76}

VELscope is an example of an adaptation of this technology that uses a handheld device that shines high-intensity blue excitation light (400–460 nm wavelengths) into the oral cavity while the provider can visualize the different fluorescence patterns. The following discussion will focus on the VELscope, pictured in Fig. 30.6.

Technique

After performing a thorough history and physical exam under normal incandescent lighting, repeat the intraoral examination while shining the VELscope light into the oral cavity. Keep the light approximately 5 cm away from the entrance of the oral cavity to maximize the area to be illuminated. While shining the light, examine the entire oral cavity through the filter that is attached to the handheld light, taking care to retract the tongue to view the lateral tongue and floor of mouth.

Under the VELscope's blue light, normal tissue fluoresces green. Malignant or dysplastic tissues will appear dark, as pictured in Fig. 30.7. However, normal tissue can be dark as well. Attached mucosa, such as the gingiva, is typically darker, as are the tonsillar pillars. Inflammation will also appear darker under the VELscope. On the other hand, hyperkeratosis appears brighter. To differentiate normal from

pathologic, malignant or dysplastic lesions are generally much darker than the aforementioned normal tissues, sharply demarcated, and are in areas at higher risk for oral cancer.

Areas that are suspicious should be palpated. Blanching of tissues by applying pressure will cause areas of inflammation that appear dark to fluoresce like normal tissue.

It is important to correlate what is seen under the VELscope with the conventional oral examination. If, after considering all the information gathered the lesion remains suspicious, then the area should be biopsied.

Indications

The VELscope, as recommended by the manufacturer, is meant to be an adjunctive screening tool, to aid in the detection of suspicious oral lesions that may require a surgical biopsy when performing a conventional oral examination. In addition, the manufacturer suggests that it may also be used to delineate the full extent of a lesion when determining margins of resection.⁷⁷

Certainly, one study of 44 patients reported that the VELscope has a sensitivity and specificity of 98 and 100% for identifying dysplasia or carcinoma verified by surgical biopsy.⁷⁸ It is important to point out that all of these lesions were visible with standard incandescent lighting and the majority of them were clinically suspicious. Unfortunately, whether the VELscope is useful in detecting suspicious lesions that are not visible, or for highlighting areas of concern within larger innocuous lesions, has not been determined. Although one small case series of three non-consecutive patients and one study screening for dysplasia in normal appearing mucosa in patients already diagnosed with oral cancer show promising results, no rigorous studies evaluating the efficacy of the VELscope in increasing early diagnosis and improving survival have been done.⁷⁹

Furthermore, it cannot be overemphasized that the VELscope was designed only to serve as an adjunctive diagnostic aid, and is not intended to

replace the surgical biopsy for diagnosing oral lesions. Therefore, it should not be used to rule out malignancy in visible lesions.

Tissue reflectance

Tissue reflectance, or chemiluminescence, is an adjunctive screening tool that has been used for detection of premalignant or malignant lesions of the cervical mucosa. Recently, this method has been applied to the identification of suspicious oral lesions as well. Two such systems are currently available, ViziLite Plus and MicroLux DL, pictured in Figs 30.8a and 30.8b respectively. Tissue reflectance is a tool meant to enhance the visibility of pathologic lesions, as shown in Figs 30.8c, 30.8d, and 30.8e. Theoretically, the increased nuclear to cytoplasmic ratio of squamous neoplasms causes increased light reflectance relative to normal epithelium, an observation that these tools attempt to take advantage of.

Technique

After performing a thorough history and head and neck examination, have the patient rinse with a 1% acetic acid solution for 30 seconds. Next use the light source of the available system to inspect the mucosa of the oral cavity, taking special care to examine areas at higher risk for oral malignancy such as the floor of mouth and tongue. The ViziLite Plus system uses a chemiluminescent light that is disposable, where as the MicroLux DL is battery operated. In either case, the manufacturer recommends that the light be kept about 0.5cm from the area of epithelium being inspected. Suspicious lesions will appear “aceto-

white”. Surgical biopsy is necessary to confirm a diagnosis of dysplasia or cancer.

Indications

Tissue reflectance technology is intended to be an adjunctive screening tool to the conventional oral examination and requires confirmation by surgical biopsy. However, it is debatable whether or not the use of these instruments provides any added benefit over the conventional oral examination under standard incandescent lighting. Although the sensitivity for highlighting potentially pathologic lesions is high, it has been observed that many obviously benign lesions, such as leukoedema and traumatic ulcers, test positive.⁸⁰ In the majority of the studies evaluating its efficacy, lesions detected by tissue reflectance were also visible under incandescent lighting.⁸⁰⁻⁸⁴ Furthermore actual sensitivity and specificity are difficult to report, as surgical biopsies were not used to diagnose all detected lesions in any of the available studies. One study by Oh and Laskin reported that the use of ViziLite actually made visualizing lesions more difficult due to the distracting highlights it created.⁸³

Brush cytology

The brush biopsy (Oral CDx from CDx Laboratories) is a technique developed as a bridge to the surgical biopsy. It is intended for oral lesions that appear innocuous and would normally not be subject to a surgical biopsy. In these situations, rather than wrestle with the pitfalls of taking the “watch and wait” approach in a high-volume practice not specialized in

Fig. 30.8 (a) ViziLite device. Photo reproduced from Zila Pharmaceuticals, Inc. with permission. (b) MicroLux/DL device. Photograph reproduced from AdDent, Inc. with permission. (e) The same lesion viewed after staining with toluidine blue.

following oral and maxillofacial pathology, the provider can perform a brush biopsy to assess the malignant potential of the lesion.

Technique

The bristled brush that is supplied by the manufacturer is applied to the lesion in question and used to scrape and disrupt the epithelium. The brush should be rotated several times over the lesion. This should be done with enough force to cause a small amount of bleeding, to ensure that the all layers of the mucosa as well as portions of the submucosa are sampled. Next, the cells need to be transferred to a glass slide by rotating the brush over the length of the slide. Following this, the manufacturer-supplied slide fixative should be applied directly to the entire slide. This should be allowed to dry for 20 minutes. This slide is then placed into a container and shipped to the CDx laboratory.

Once received by the laboratory, the harvested cells are analyzed by a computer, which selects out cells that are potentially malignant. These cells are then reviewed by staff pathologists, using both digital images and standard microscopy. The results are reported to the provider as “positive”, “atypical”, “negative”, or “incomplete”. Positive and atypical lesions are then subjected to a surgical biopsy. Lesions reported as incomplete do not have all of the cell layers. A repeat brush biopsy is recommended by the manufacturer.

Indications

The brush biopsy is intended to be an adjunct diagnostic tool, as opposed to a screening tool. In other words, in lesions that have been detected, the brush biopsy is meant to assist in establishing a diagnosis.

Because the brush biopsy is targeted towards those lesions that clinicians might not necessarily biopsy, it must be highly sensitive for detecting malignancy in lesions that are clinically innocuous. In order to accurately demonstrate this advantage, the population investigated must have lesions that are not already highly suspicious for malignancy, and all lesions in the population must be subjected to the gold standard: surgical biopsy. Unfortunately, the majority of available studies evaluating the brush biopsy are not selective for the target population and include likely or known-to-be malignant lesions.^{85–91} In addition, in most of the studies, lesions that were reported as “negative” based on the brush biopsy were not confirmed by a surgical biopsy. Only in one study by Scheifele *et al.* did all lesions have both a brush and surgical biopsy.⁹² The sensitivity and specificity reported by this paper were 92.3% and 94.3%, respectively. However, lesions that were highly suspicious for malignancy were included in this analysis. Therefore, the actual sensitivity may be lower due to spectrum bias. Regardless, a false-

negative rate of 7.7% is unacceptably high for an adjunctive diagnostic tool.

It is the authors’ opinion that the current literature does not support adding the brush biopsy to the diagnostic armamentarium. At best, it leads to a delay in the definitive surgical biopsy. At worst, it has a nearly 8% false-negative rate, leading the patient and provider to the mistaken impression that the patient is disease free. Some specialists have argued that it may have a role in the surveillance of patients with a history of oral cancer or dysplasia that might otherwise require multiple biopsies.⁹³ However, it is the authors’ opinion that it is exactly in this population that the threshold for biopsy should be lowered as they have the highest risk of malignant transformation.

Management of premalignant disease

In oncology, it is a commonly held tenet that cancers that are detected early can be treated more effectively and with less morbidity, thus increasing a patient’s chances for survival. It has been theorized that cells that ultimately become malignant must go through a succession of genetic changes that allow them to be derailed from the usual growth restrictions of normal cells in tissues, a process described as multistep carcinogenesis.^{94,95} Thus, if a cancer can be detected early, before it has acquired all of the mutations necessary for invasion and metastasis it may be possible to successfully treat the disease locally. Certainly, this has been shown to be true in several cancers including colorectal cancer and cervical cancer.

However, in order for the same to be true for oral cancer requires an understanding of the natural history of premalignant oral lesions. Furthermore, the natural history of the disease must be such that the premalignant lesion progressively becomes more dysplastic, becomes invasive, and only then does it have the ability to metastasize. Recent studies in breast cancer indicate that this paradigm may not be true and that metastasis can occur before invasion is seen on histopathology.⁹⁶ Regardless, there also must be an intervention that can remove the premalignant disease in such a way that improves survival.

For some time, it has been observed that certain oral lesions, specifically leukoplakias and erythro-leukoplakias, have the potential for malignant transformation. Unfortunately, the natural history of oral cancer and leukoplakia is convoluted. Not all oral squamous cell carcinoma are preceded by leukoplakias, not all leukoplakias progress to oral cancer, and some leukoplakias are much more aggressive than late-stage cancers. The following sections will briefly summarize what is known about the natural history, the surgical treatment, and medical treatments for premalignant disease.

Natural history of premalignant disease

Several lesions within the oral cavity have been said to be premalignant. They include leukoplakia, erythroplakia, lichen planus, and submucous fibrosis, among others. However, only leukoplakia and erythroplakia contribute significantly to the incidence of premalignant lesions and oral cancer.⁹⁷

Leukoplakia is a descriptive term for a white patch or plaque that is adherent to the oral mucosa and cannot be wiped off. It is a term used only when other diagnoses with similar appearances, such as lichen planus, candidiasis, white sponge nevus, frictional keratosis, and leukoedema, have been ruled out. Similarly, erythroplakia and erythroleukoplakia are descriptive terms for red lesions and mixed red and white lesions.⁹⁸

The worldwide prevalence of oral premalignant disease is estimated to be 1–5%^{99–101} and the prevalence of oral leukoplakia is calculated to be 2.6%.¹⁰² Naturally, prevalence varies significantly from region to region, depending on local risk factors.^{103–107} It is most commonly found in patients 30–70 years old, although younger patients are affected as well. Men are more commonly affected than women, although the ratio between the genders varies greatly depending on the population.

Overall, the buccal mucosa is the most common location for leukoplakia to occur.^{103,108–110} However, the site of the leukoplakia seems to be correlated to types of tobacco habits practiced by the patient population of interest. For example, parts of India where pan (betel nut with tobacco and slaked lime) chewing is common, 65% of leukoplakias are on the buccal mucosa. On the other hand, regions where reverse smoking is more prevalent, leukoplakias are more commonly found on the palate.¹⁰³ In addition, although buccal mucosa is the most common location, leukoplakias of the tongue and floor of mouth are most at risk for malignancy.^{110–113}

Partly because the definition of leukoplakia is one of exclusion, it includes a heterogeneous group of lesions with different clinical appearances and histologic findings. As such, the etiology of leukoplakia is multifactorial. The vast majority of leukoplakias have been correlated to tobacco use.^{101,105,108,114–116} As mentioned above, these are commonly found on the buccal mucosa or mandibular vestibule (snuff dipper's pouch) and are often reversible with cessation of the tobacco habit.¹¹⁷ However, 4–38% of leukoplakias are idiopathic.^{108,118–120} It is precisely these idiopathic leukoplakias that have the greatest potential for malignant transformation. As many as 5% of idiopathic leukoplakias are squamous cell carcinoma on initial biopsy, and another 10–15% are at risk for transformation.¹¹⁰ Erythroplakia and erythroleukoplakia carry even greater risk for developing malignancy.¹²¹

In addition, Silverman *et al.* have described a unique form of leukoplakia that has very high rates of

malignant transformation called proliferative verrucous leukoplakia (PVL).¹²² These lesions tend to appear initially as hyperkeratosis. However, they aggressively spread to include large areas of the oral cavity and often are multifocal. Although slow growing, they are persistent, and invariably recur after being excised. Over time, they can become exophytic and verrucous in appearance. Even as these lesions become progressively malignant in behavior, the histopathology can often remain as benign hyperplasia. Therefore, these lesions should be evaluated by their clinical behavior and not their pathology. Malignant transformation is expected if patients are followed for enough time, with rates of transformation at 60–100%.^{110,120,122,123}

It has been suggested that the human papilloma virus (HPV) may also play a role in leukoplakia and premalignant disease in the oral cavity, as is the case with oropharyngeal cancer.¹²⁴ Whether certain HPV subtypes increase the risk of developing oral cancer remains a contentious issue. Recent studies using polymerase chain reaction (PCR) assays to detect HPV DNA in oral cancers have not shown a relationship between oral squamous cell carcinoma and HPV positivity.^{125–127} However, other studies have shown a relationship.^{128–132} One of the difficulties with establishing a relationship between HPV and oral cancer is confusion with the nomenclature. The distinction between oral cancer, oropharyngeal cancer, and head and neck cancer is often not made explicit or is simply disregarded. In addition, PCR assays for HPV in oral cancer are not nearly as sensitive as they are for cervical cancer. At the present time, the general consensus is that HPV is not strongly associated with the development of oral cancer.¹³³

On histopathologic analysis, leukoplakias are also heterogeneous in presentation. Biopsy findings can be variable, demonstrating hyperkeratosis, varying grades of dysplasia, carcinoma *in situ*, or invasive squamous cell carcinoma. The discovery of dysplasia may provide some diagnostic benefit, as patients with biopsy-proven dysplasia are at higher risk for malignant transformation.¹³⁴

The grading of dysplasia is also helpful in predicting risk, because as many as 36% of severe dysplasias become invasive cancer.^{110,119,135} Although there are a number of dysplasia grading systems that have been described, the most commonly used system is as follows. Mild dysplasias have architectural changes confined to the basal third of the full thickness of epithelium. Moderate dysplasias are up to two thirds the full thickness of epithelium. Severe dysplasias are greater than two thirds of the full thickness, but without invasion through the basement membrane. Consideration is then given to the degree of cellular atypia. These features include increased nuclear cytoplasmic ratios, increased or abnormal mitoses, or pleomorphism of nuclei.

Unfortunately, oral squamous cell carcinoma does not always follow a natural progression from mild

dysplasia to severe dysplasia to invasive carcinoma. Cancer can also be found in hyperplasia or mild dysplasia. One group found that patients with mild dysplasia had the same transformation rates as those with severe dysplasia.¹³⁶ Also, the grading of dysplasia can be difficult, and there is significant inter-examiner and even intra-examiner variability. Several studies have found poor agreement between pathologists.^{137–140} As such, using presence or grade of dysplasia to quantify risk for transformation is not straightforward. An understanding of the biology of oral cancer development is necessary.

Genetic progression to oral cancer

Epithelial tissues, whether they are oral mucosa or skin, are able to renew themselves as they continuously slough off cells. These tissues are able to do so due to a tightly regulated system of self-renewal involving stem cells that reside in the basal layer of the epithelium. Each of these stem cells, when appropriately stimulated, divides to produce identical cells called daughter cells. One of these daughter cells undergoes further divisions and differentiates into mature squamous cells. The other of the daughter cells remains in the basal layer as a stem cell. Once the tissue is renewed, the system autoregulates and the stem cells become dormant.

Because these epithelial stem cells remain in the basal layer of the epithelium rather than being sloughed off, they are potentially exposed to carcinogens or other genetic insults for the lifetime of the patient. It is believed that genetic injury to epithelial stem cells leads to loss of this tight tissue regulation.¹⁴¹ This loss of regulation results in a clonal expansion of epithelial stem cells with the ability to self-renew, that ultimately creates a field of potentially premalignant cells that are susceptible to further mutations, the so-called “field cancerization” phenomenon described by Slaughter *et al.*¹⁴² Amongst this field, further genetic injury will lead some of these cells to become more derailed from regulatory mechanisms as they acquire mutations that promote proliferation, inhibit tumor suppressor genes, stimulate angiogenesis, and allow invasion.

It is estimated that a minimum of five mutations are required for carcinogenesis to occur.¹⁴³ Califano *et al.* proposed a model for progression of head and

neck squamous cell carcinoma defining early and late mutations that lead to carcinogenesis, which is shown in Fig. 30.9.¹⁴⁴ Since Califano’s article, a plethora of work has been devoted to identifying other common genetic mutations that predispose to transformation and invasion.¹⁴⁵ However, how they fit into the natural history of carcinogenesis and whether the knowledge will affect clinical practice is yet to be determined.

At times, the progressive accumulation of genetic injury leads to microscopic and macroscopic changes, such as leukoplakia. Unfortunately, these genetic alterations can also occur without any phenotypic changes. This significantly handicaps the surgeon’s ability to fully excise a lesion or tumor. Certainly, it has been known for some time that even histologically clear margins demonstrate mutations that ultimately lead to increased rates of recurrence.^{146–152} In the setting of premalignant disease, excision of a leukoplakia may only be removing a small portion of the field of defective cells. This makes oral cancer screening and surveillance difficult. This may also explain the frequency of local recurrences or second primary tumors in contiguous areas.

Surgical management of dysplasia

The most common method for managing biopsy-proven dysplasia of the oral cavity is local surgical excision. However, it is important to recognize that there is currently no evidence that surgical excision is effective in removing all premalignant cells. Nor is there any evidence that suggests excision prevents recurrence of the dysplasia, prevents transformation, or reduces mortality. In actuality, nearly 30% of dysplasias recur in the same location after excision.¹⁵³ A recent Cochrane review underscored this lack of evidence of therapeutic benefit, noting that there is not a single randomized controlled trial evaluating the efficacy of surgical treatment of dysplasia.¹⁵⁴ The majority of the literature on the subject is retrospective, does not use controls, and has conflicting results. One retrospective study that does have a control group found no significant difference in rates of transformation.¹⁵⁵ Furthermore, excision of dysplasia is like any other surgery and has associated morbidity and risks.

Despite this, there are certainly reasons to recommend surgical excision. The primary reason is that

Fig. 30.9 Genetic progression of head and neck cancer. Adapted from Califano *et al.*¹⁴⁴

excision of a dysplastic lesion provides a valuable histologic diagnosis.¹⁵⁶ As mentioned above, 5% of idiopathic leukoplakias already have invasive cancer at the initial biopsy.¹¹⁰ In addition, incisional biopsies are subject to sampling error, and dysplasia or carcinoma can be easily missed. Some studies have reported that over 10% of lesions diagnosed by incisional biopsy as dysplasia demonstrated invasive carcinoma after excision.^{157,158}

Medical management of dysplasia

Given that surgery is probably ineffective in treating dysplasia, especially in the setting of field cancerization, the use of systemic or topical chemopreventive measures is particularly attractive. Several agents have been studied for this purpose, including vitamin A and retinoic acid, taken systemically or applied topically, systemic beta-carotene, systemic lycopene, topical ketorolac, and topical bleomycin. Although beta-carotene, lycopene, vitamin A, and retinoids showed a small amount of benefit, they were associated with adverse effects and had high recurrence rates with cessation of the therapy. A recent Cochrane review concluded that no currently studied chemopreventative measures are of any benefit for treating premalignant disease or preventing malignant transformation.¹⁵⁴

Summary of management of dysplasia

The authors recommend, therefore, that all moderate to severe dysplasias be excised, if it is anatomically feasible. This should be done using a scalpel, as the use of lasers or electrosurgery eliminates the ability to perform a histopathologic analysis. Patients with mild dysplasia should be counseled that their risk for transformation is likely to be less, but still present. These patients can undergo expectant management and should be educated to self-monitor for phenotypic changes or the development of concerning symptoms, such as pain, paresthesia, or ulceration. Regardless of the therapy provided, a patient with biopsy-proven dysplasia should be followed by clinical exam indefinitely.

Margin assessment

The primary aim of surgical resection of cancer of the head and neck is to remove all macroscopic and microscopic tumor cells. In doing so, the hope is that either all of the cells with potential for invasion have been removed, or that only a small number of cells with premalignant or malignant characteristics remain such that the patient's own immune defenses may eliminate them. The completeness of a surgical resection is typically assessed by measuring the margin clearance.

Margin assessment involves the histologic measurement of a cuff of normal tissue beyond the most invasive portion of the tumor. For oral squamous cell carcinoma (SCC), a clear margin is conventionally defined as 5 mm of normal tissue beyond all tumor margins, a close margin as less than 5 mm but without tumor cells involving the margin, and positive if tumor cells are seen at the margin.^{159–161} However, these designations are arbitrarily defined.¹⁶² Patients with close or positive surgical margins have been shown to have worse local control of disease, and adjunctive radiation therapy or additional surgical resection is generally offered.^{159–161,163} Thus, close or positive margins are regarded as poor prognosticators, with 5-year survival decreasing from 60% to 52% and local recurrence rates increasing from 18% to 36%.¹⁶¹ However, recent studies have suggested that close or positive margins may not actually be indicators of lack of surgical completeness, but rather it may represent an increased invasiveness of a particular tumor.¹⁶⁴

Frozen section analysis

The pathologist performs the margin assessment on the permanent specimen after the ablative surgery. However, it is desirable to assess the adequacy of a resection intraoperatively, so that the surgeon may decide whether to increase the volume of resection if allowable. Frozen section analysis is used for this end.

Frozen section analysis is typically performed in the following way. Intraoperatively, after the main tumor specimen has been resected, the surgeon cuts sections off of the mucosal and deep margins, especially in areas of the surgical bed that are concerning for remaining tumor cells. These specimens are submitted to the pathologist for frozen section analysis. The pathologist will freeze the specimens, and then slice them into 5–7 µm sections with a microtome. These sections are then adhered to glass slides, treated with fixatives, and stained with hematoxylin and eosin. These slides are then reviewed to verify if any tumor cells remain in the margin.

There are two main drawbacks to this form of analysis. The first is that it is subject to sampling error. Because the surgeon cannot sample the entire margin of the tumor resection bed, whether a positive margin can be detected intraoperatively depends entirely on whether the surgeon can predict where the tumor cells remain. The second shortcoming is that close margins will not be detected.

For these reasons, some surgeons argue that frozen section analysis is not beneficial and simply prolongs the length of the operation. Ord and Aisner reported that, although frozen sections were 99% accurate in diagnosing SCC when compared to permanent sections, only 1 of 49 patients (2%) had a positive margin diagnosed by frozen section that led to extending the resection margin.⁴⁵ This group argued

that the routine use of frozen section analysis might not be worthwhile.

However, given the lack of a viable alternative to frozen section analysis for intraoperative assessment of margin status, the authors still recommend the routine use of frozen section analysis, keeping in mind the limitations with this technique. When sampling tissue for frozen section analysis, the surgeon should take care to select areas where tumor invasion is most likely to have compromised the margin. This invariably will occur at the deep margin. When treating tumors of the retromolar trigone or posterior maxilla, it is often the most posterior and deep margin that is most difficult to clear and, because of this, is the most appropriate area to sample. The surgeon should also keep in mind the tissue planes that are most susceptible to rapid tumor invasion. SCC does not uniformly invade with a broad front radiating from an epicenter. Rather, SCC will invade irregularly, along the path of least resistance. For resections involving bone, this may be the bony margin or marrow space. For tongue cancers, this is often along skeletal muscle. If there is nerve associated with the tumor, invasion may be perineural.

Tissue shrinkage in margin analysis

One major hurdle with using clear margins as a treatment goal is that margin lengths are subject to tissue retraction and shrinkage. Therefore, when a surgeon measures and resects a 1 cm surgical margin from the edge of the tumor, this length will invariably shrink to a shorter margin on pathology. Johnson *et al.* reported in a dog model a mean shrinkage of 34.5% in deep tongue margins, with most of the shrinkage occurring immediately after resection.¹⁶⁵ Mistry *et al.* reported similar results in their study in humans.¹⁶⁶ Furthermore, the shrinkage that occurs is not uniform and, as one would expect given the complex anatomy of the oral cavity, varies from location to location. In a retrospective study, our group has reported that tumors of the retromolar trigone and mandible have the greatest discrepancy between the surgical and pathologic margin.¹⁶⁷

Because of this variable margin shrinkage, it can be difficult to achieve clear margins predictably. Even when a surgeon includes a generous cuff of healthy tissue around the tumor, tissue shrinkage can result in a close margin. Some have suggested that the fact that margin shrinkage occurs should be reassuring to the surgeon in that a close margin after shrinkage occurs is, in actuality, a clear margin. However, the authors strongly disagree with this interpretation, recalling that all of the literature relating margin status to local control of disease and outcomes are based on the final pathologic margin, presumably after any margin shrinkage would have occurred. Therefore, rather than being reassuring, the presence of tissue shrinkage should prompt the surgeon to be more careful in planning the surgical resection, being more

generous in areas where the surgeon feels shrinkage is more likely to occur. Naturally, this is exceptionally difficult, given that even the most experienced head and neck surgeons report rates of close or positive margins at 33–43%.^{45,159,168}

Molecular techniques in margin analysis

Surgical resection with a margin of normal tissue is important because cells that appear normal on histopathology may still harbor mutations that predispose the cell towards malignant behavior. The goal, then, is to surgically remove as many of these normal appearing malignant cells when resecting the tumor. Brennan *et al.* elegantly demonstrated that mutations in TP53, a tumor suppressor gene that is commonly mutated, could be found in margins that are clear.¹⁴⁶ These mutations increased the risk for local recurrence in the same location. Similarly, Nathan *et al.* demonstrated that overexpression of the translation factor eIF4E is an early step in malignant transformation. Furthermore, detection of eIF4E in histopathologically clear margins using immunohistochemistry is correlated with high recurrence rates.^{148,150,169} Therefore, the development of molecular techniques to detect these mutations in normal appearing tissue would be of great value in aiding surgical completeness when possible.

However, a number of difficulties have prevented routine use of molecular testing outside of a research setting. The most important hurdle is that the majority of studies using molecular markers only test one or a handful of genetic mutations. Unfortunately, oral SCC is heterogeneous. Even mutations of TP53, the most common mutation associated with oral SCC, are only present half of the time.^{170,171} To address this problem, the use of microarrays for molecular margin analyses are actively being researched to simultaneously look for aberrations in expression or copy numbers across the entire genome. Although the use of these molecular techniques is still in its infancy, the potential is substantial. Chung *et al.* reported that, using microarrays to profile head and neck SCC, they were able to predict risk of neck metastases in 80% of their patients, but only after excluding patients with oral SCC, underscoring the heterogeneity of this disease.¹⁷²

Summary

Surgical pathology remains the gold standard for diagnosis of tumors of the head and neck. However, in order to fully utilize the expertise of our pathology colleagues, the surgeon must be able to effectively communicate with the pathologist, provide the pathologist with an adequate and appropriately oriented specimen, and understand the limitations of pathology and how to interpret results. Pathologists

have several tools with which they can analyze tissues; which tools they choose depends on the clinical question that the surgeon presents to them. Depending on the context, the same slide can be interpreted differently. Surgeons often rely on frozen sections to preliminarily assess the completeness of a resection, but the efficacy of this tool depends on the surgeon's ability to select the appropriate specimens for the pathologist to analyze. Pathologic processing can cause dimensional changes in tissue specimens. The surgeon must understand and consider this in order to adequately remove tumor. The next frontier for pathology is the use of molecular techniques on tissue to improve margin analysis and stratify risk for recurrence, metastasis, and, more importantly, prognosis. As these technologies develop and become readily available, surgeons and pathologists must learn to incorporate them into the diagnosis and treatment of their patients.

Case presentations

The case of the inappropriate use of a technique

Patient A was a 56-year-old woman who was seen in our department for a fifth opinion regarding a possible diagnosis of ameloblastoma of her left lower jaw. She reported a 5-month history of a painless swelling at the angle of her left lower jaw. Thinking that this was a dental infection, she went to see her dentist, who noted an unusual radiolucency on dental radiographic exam. The dentist consequently referred her to see a specialist. She saw a number of different specialists, and ultimately underwent an FNAB of the left mandibular swelling. The cytopathologist noted "malignant appearing epithelial cells", offering a differential diagnosis of ameloblastoma or myoepithelial tumor. She was then offered mandibular resection and reconstruction with a fibular free flap as treatment for this lesion by the specialist at the academic center nearest to where she lived. Seeking another opinion, she was referred to the University of California, San Francisco.

Outside of the swelling, she denied any appreciable symptoms, such as pain, paresthesia, dysphagia, odynophagia, otalgia, voice changes, weight loss, fevers, chills, or malaise.

Her past medical history was only significant for systemic lupus erythematosus, for which she took Plaquenil. Her surgical history only included third molar extractions in the distant past. Her family history was significant for her mother being diagnosed with lung cancer in her fifties with no history of tobacco use. The patient was also a never smoker. She drank alcohol occasionally. She denied any history of illicit drug use.

On examination, the patient appeared well. However, she had obvious facial asymmetry involv-

ing her left mandible, as shown in Fig. 30.10. A mass measuring approximately 4×3 cm was clearly visible at the angle of her left mandible. The overlying skin was entirely normal. The lesion was solid, fixed to the surrounding tissues, and non-tender. There was no palpable thrill or audible bruit. On bimanual palpation, with one examining finger placed intraorally, a clear demarcation could be appreciated between the mandible and the lesion. No buccal expansion of the mandible was appreciated. The rest of her oral exam was unremarkable.

A series of radiographs ordered by her previous consultations were reviewed. As shown in Fig. 30.11, her dental panoramic tomogram shows a poorly defined osteolytic lesion at the angle of her left mandible, inferior to the inferior alveolar nerve canal. Fig. 30.12 shows selected views from her cone-beam CT. One can clearly see that the lesion was not associated with her dentition.

Having reviewed the patient's history, exam, radiographic studies, and cytopathology report, it was clear that a number of things did not make sense, particularly with her diagnosis of ameloblastoma. Ameloblastomas are benign odontogenic tumors. Although epithelial in origin, they typically are not

Fig. 30.10 Facial photograph of patient A. Note the swelling of the left angle of mandible.

Fig. 30.11 Initial dental panoramic tomogram of patient A. Note the poorly defined radiolucent lesion located at the angle of the left mandible, inferior to the inferior alveolar nerve canal.

Fig. 30.12 Selected images of the cone-beam CT of patient A.

described as containing “epithelial” cells and certainly are not “malignant”. Very rarely, a patient may present with ameloblastic carcinoma, which is malignant. However, being odontogenic, it would not be located inferior to the inferior alveolar nerve canal. Therefore, the patient’s diagnosis seemed implausible.

Our differential diagnosis would include metastatic cancer, salivary gland neoplasms, metastatic lymphadenopathy, and lymphoma. The most common cancers to metastasize to bone in women are breast, lung, liver, renal, and colon cancers. This diagnosis fits well, given the appearance of the lesion, the location at the angle of the mandible, which is the most common site for bony metastasis in the maxillofacial region, and the family history of lung cancer in her non-smoking mother. For salivary gland neoplasms, it would be unusual for benign tumors to cause osteolysis of the mandible. Our differential diagnosis for malignant salivary gland neoplasms would include mucoepidermoid carcinoma, adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma, and, given the cytopathology report, epithelioid myoepithelial carcinoma. The most common cancer to metastasize to the cervical lymph nodes would be head and neck SCC. However, the exam did not fit this diagnosis well. Much lower on the differential we might consider infectious processes, such as chronic osteomyelitis, tuberculosis, cat scratch disease; however, the exam also did not seem to fit well with any of these.

Regardless, it was clear that the next step in the evaluation would be to perform an incisional biopsy to obtain an adequate tissue sample for diagnosis. Given the difficult location and the intraosseous component, she was scheduled for this procedure under general anesthesia in the operating room.

Frozen sections taken at the time of the operation demonstrated an epithelial neoplasm. The initial review of the permanent specimen showed an infiltrating glandular malignancy, consistent with a metastatic adenocarcinoma. To determine the origin, a battery of stains was performed. Pancytokeratin stains were positive, confirming the epithelial nature of the malignancy. A positive CK7 and negative CK20 profile was suggestive of lung, thyroid, salivary gland, breast, and gynecologic tumors. TTF-1 positivity narrowed the diagnosis to thyroid or lung. Negative mammaglobin and ER argued against breast cancer. Finally, negative synaptophysin and chromogranin argued against a neuroendocrine carcinoma. These results were most consistent with a diagnosis of metastatic lung adenocarcinoma. Given that the patient already had metastasis to a distant site, she was diagnosed with a Stage IV adenocarcinoma of the lung.

A CT of the chest was performed, pictured in Fig. 30.13, which demonstrated a 2.6×1.8 cm spiculated lesion of the right upper lobe with a 6–7 mm perivascular lymph node. She was subsequently

referred to a cardiothoracic surgeon and a medical oncologist. She ultimately underwent treatment with chemotherapy. She had complete resolution of both the mandibular and right upper lobe lesions. Unfortunately, soon after, she was found to have local recurrence of her lung adenocarcinoma.

There are a number of learning points that should be highlighted with this case. The first is that the history and physical exam are critical. The family history of a non-smoking mother diagnosed with lung cancer should alert the clinician to include metastatic cancer in the differential diagnosis, especially given the location and clinical findings. The examination findings were not consistent with an odontogenic tumor, so it should not be included on the differential diagnosis. Second, one must choose the appropriate test for the patient. An FNAB is not the diagnostic test of choice for an osteolytic lesion in the mandible. It should not be used to definitively diagnose ameloblastoma. Third, the surgeon must be able review the pathology report, interpret the description in the report, and place the pathology in context of the patient. Although the pathologist is the one reading the slide, the responsibility to come to the correct diagnosis and treatment depends solely on the surgeon. A surgeon reading the word “malignant” on a report with a diagnosis of ameloblastoma should immediately begin to question whether that report is valid. If any diagnosis appears on a report that does not fit well with the initial differential diagnosis, it should be considered suspect and the pathology should either be repeated or reviewed again. This also emphasizes the necessity of excellent communication with the pathologist and using a pathologist with experience in interpreting head and neck diseases. Although this mistake probably did not affect the patient’s prognosis, she would have needlessly undergone a major debilitating surgery if the mistake had not been corrected.

The case of the inadequate specimen

Patient B was a 93-year-old woman referred to the University of California San Francisco’s Department of Oral and Maxillofacial Surgery for evaluation of a large exophytic verrucous mass on her hard palate. She initially noticed a lesion in her upper jaw approximately 1 year prior when her maxillary denture was

Fig. 30.13 Chest CT of patient A. Note the 2.6×1.8 cm spiculated lesion of the right upper lobe and the 6–7 mm perivascular lymph node.

not fitting as well. She went to see her dentist to see if her denture could be adjusted and the dentist noticed the verrucous mass on her left hard palate, part of which was underneath the maxillary denture. She was then referred to her local surgeon for a biopsy. She underwent a biopsy in the clinic. The specimen was reviewed by an outside pathologist as “papillomatous hyperkeratosis” with “no evidence of malignancy”. The surgeon, reassured, diagnosed her with a benign papilloma and sent her back to her dentist to have her denture remade. However, her general dentist was still quite concerned, and asked the surgeon to repeat the biopsy. Again, the surgeon performed a biopsy in the clinic, and again, the diagnosis came back as a benign papilloma. Unconvinced, the general dentist referred the patient to the University of California, San Francisco.

She denied any pain, paresthesia, dysphagia, odynophagia, otalgia, voice changes, weight loss, fever, chills, or malaise. She did report that she had occasional bleeding from the area. Her main concern was her ill-fitting denture.

Her past medical history was significant for a history of colon cancer treated by partial colectomy, hypertension, hypercholesterolemia, stable angina treated with nitroglycerin, and bronchitis. Her surgical history was significant for her partial colectomy

and cataract surgery. She was taking Zocor, nitroglycerin, and Benicar. She denied ever smoking and she only rarely drank alcohol. She denied any history of illicit drug use. Her family history was non-contributory.

On examination, she had no cervical or submandibular lymphadenopathy. Her facial exam revealed no asymmetries or skin lesions. Her oral exam, with her dental prostheses removed, demonstrated a large exophytic verrucous lesion, approximately 4×6 cm in size, which extended from the left hard palate and maxillary alveolus posteriorly into her oropharynx, as shown in Fig. 30.14. In addition, there was a 2×1 cm verrucous lesion on her left mandibular gingiva in the area of the left retromolar trigone, within an intervening area of normal but telangiectatic mucosa between the mandibular lesion and the maxillary lesion.

A dental panoramic tomogram (Fig. 30.15) was taken that did not show any evidence of bony involvement in the mandible. The maxilla was atrophic, and it was difficult to appreciate whether any bony invasion had occurred.

On review of the pathology reports, which diagnosed the lesion as “benign polypoid and papillary squamous mucosa with acute inflammation and reactive changes, consistent with squamous papilloma”, it was noted that the dimensions of the first biopsy specimen were “ $0.7 \times 0.5 \times 0.3$ cm” and of the second specimen were “ $0.5 \times 0.4 \times 0.3$ cm”.

To summarize, Patient B was a 93-year-old woman with a large aggressive verrucous lesion of the maxilla extending into her oropharynx and mandible. Her previous diagnosis of benign papilloma, or “oral wart”, was not consistent at all with her clinical presentation, with papillomas being typically much smaller. Our differential diagnosis included oral SCC, verrucous carcinoma, or proliferative verrucous leukoplakia.

Recalling that the previous biopsy specimens were both only 0.3 cm in depth, short of the minimum 5 mm depth required, we made the determination that more tissue would be needed for an adequate diagnosis. In the clinic, under local anesthesia, the

Fig. 30.14 Intraoral photograph of patient B. Note the large exophytic verrucous lesion of the left maxilla.

Fig. 30.15 Initial dental panoramic tomogram of patient B.

patient had three surgical biopsies using a punch biopsy that was carried to the hub of the cutting edge and down to the bone of the maxilla. These specimens were then sent to our oral pathologists for review, and the patient was diagnosed with oral SCC.

The patient was presented at the University of California, San Francisco Head and Neck Tumor Board and was staged with a T4N0Mx SCC of the left maxilla and mandible. The head and neck CT is shown in Fig. 30.16. She was taken to the operating room and underwent a left selective neck dissection, left maxillectomy, left mandibular gingiva excision, and left oropharyngeal excision. She was reconstructed with a split-thickness skin graft and surgical obturator.

The first learning point from this case is that, as mentioned in the previous case, the surgeon must interpret the pathology report in the context of the patient's clinical presentation. A diagnosis of an oral wart is not consistent with a 4 × 6 cm lesion extending into the pharynx and mandible. This should prompt either a repeat biopsy or having the pathology reviewed again. The second learning point is that the surgeon needs to give the pathologist adequate material to work with. A surgical biopsy needs to be a minimum of 5 mm in depth. With exophytic verrucous lesions, this depth should be greater considering that much of the verrucous portion of the lesion is keratinized epithelial tissue and the pathologist needs to see invasion into the submucosa to establish the diagnosis of cancer. The outside surgeon, reticent to aggressively incise into a lesion on a 93-year-old woman, only performed an epithelial shave of the lesion. Although this was certainly more comfortable (a fact that was confirmed by the patient, who reported that our biopsy was much "deeper"), it delayed the correct diagnosis for this patient.

The case that benefited from an oral pathology consult

Patient C was a 7-year-old girl who was referred to the San Francisco General Hospital, Department of Oral and Maxillofacial Surgery for evaluation and treatment of an incidental finding of an osteolytic lesion in her left mandible. The lesion was first dis-

Fig. 30.16 Head and neck CT of patient B. Note the large enhancing lesion in the area of the left maxilla with evidence of bony invasion, as highlighted by the yellow arrows.

covered during a routine dental visit on a dental radiograph. At that time, a dental panoramic tomogram was taken that demonstrated a well defined radiolucent lesion in the body and ramus of the left mandible. This lesion was causing the displacement of her tooth #19 (Universal numbering system) or 4–6 (FDI) and the developing follicle of tooth #18 (Universal numbering system) or 4–7 (FDI). She was subsequently referred to San Francisco General Hospital.

The patient was entirely asymptomatic. She did not complain of any pain, paresthesia, dysphagia, odynophagia, dyspnea, otalgia, weight loss, fever, or chills. Her past medical history, past surgical history, social history, and family history were unremarkable.

On examination, she was a well appearing young girl in no acute distress. She had no cervical or sub-mandibular lymphadenopathy. She did not have any visible facial asymmetry or cutaneous lesions. However, on clinical examination, she was found to have bony hard expansion of the body of the left mandible. On examination of her oral cavity, her tooth #19 (Universal numbering system) or 4–6 (FDI) was somewhat displaced. On bimanual examination, her buccal expansion was hard, with no evidence of cortical perforation.

Her dental panoramic tomogram was reviewed (not pictured) which demonstrated a 3 × 2 cm multilocular radiolucency in the body and ramus of the left mandible, as previously described.

The initial differential diagnosis for a slow growing expansile, well defined, osteolytic lesion of the mandible in a 7-year-old girl would include dentigerous cyst, keratocystic odontogenic tumor, odontogenic myxoma, and ameloblastic fibroma. Ameloblastoma might also be included, but given the patient's age it would be much lower in probability. Given the indolent nature of the patient's history, we were reassured that it was unlikely to be malignancy. As all of these lesions are diagnosed and treated surgically, the patient was planned for an incisional biopsy in the operating room under general anesthesia. The decision to go to the operating room and use general anesthesia was made because of the lesion's location as well as the patient's age. In addition, given that the patient would already be intubated and anesthetized, she also was to have a CT performed following the biopsy.

The frozen sections were reassuring, consistent with a benign pathology. The final pathology diagnosed the lesion as an ameloblastoma. The CT (Fig. 30.17) agreed with the previous radiologic findings, showing a 1.7 cm osteolytic lesion in the left mandible associated with the crown of the developing tooth #18.

However, we felt that it would be prudent to get a second opinion on the pathologic diagnosis. Ameloblastoma was much lower on our differential, given the patient's age. Ameloblastic fibroma, which could easily be confused for ameloblastoma, was

Fig. 30.17 Head and neck CT of patient C. Note the osteolytic lesion causing cortical expansion in the area of the developing left mandibular second molar, as highlighted by the yellow arrows.

Fig. 30.18 (a) Micrograph of ameloblastoma. (b) Micrograph of ameloblastic fibroma. Note the significant myxoid connective tissue component.

much more likely. Fig. 30.18a shows a representative micrograph of an ameloblastoma compared to Fig. 30.18b, an ameloblastic fibroma. The distinction is critical, as ameloblastoma is treated with a wide resection, whereas ameloblastic fibroma can be effectively treated with enucleation. Consequently, we had the slides reviewed a second time by our colleagues in oral pathology.

On the second review, it was noted that although there were numerous strands of odontogenic epithelium very similar to ameloblasts, there was also a

prominent myxoid connective tissue component within the tumor as well. Given that ameloblastoma is an epithelial tumor in origin and ameloblastic fibroma is a mixed epithelial and mesenchymal tumor, the diagnosis of ameloblastic fibroma was made.

The patient was then treated with extraction of tooth #19 and enucleation and curettage of the ameloblastic fibroma. The patient recovered uneventfully. She was seen for regular follow-up visits and continues to remain disease free. A follow-up dental panoramic tomogram (not pictured) demonstrated near complete resolution of the lesion.

Upon reviewing this case, it is important to take away two learning points. The first is that if there is any question with regard to the diagnosis, one should not hesitate to consult a second opinion. The second point is that, given the rarity of these lesions, it is critical that the specimen be reviewed by a pathologist with experience in this area. This is especially true when the correct diagnosis can be the deciding factor between a minor surgical procedure and a mandibular resection.

Chapter 31

Cystic Lesions of the Jaws

Nicholas M. Goodger and Christopher W. Hendy

This chapter describes the range of cystic lesions, common and uncommon, of the hard and soft tissues of the jaws and neck that present to dentists and oral and maxillo-facial surgeons. Cystic lesions associated with the salivary glands and those from odontogenic tumors are considered in their respective chapters. For each condition the etiology, presentation, radiographic findings, and diagnosis are presented along with the accepted treatment for each condition.

Odontogenic cysts, 621
 Apical or radicular cysts, 621
 Residual cysts, 622
 Lateral periodontal cysts, 622
 Dentigerous cysts, 623
 Eruption cyst, 623
 Gingival cysts, 624
 Odontogenic keratocyst (primordial cyst, keratocystic odontogenic tumor), 624
 Calcifying epithelial odontogenic cyst, 624

 Sublingual dermoid and dermoid cysts, 625
 Branchial lymphoepithelial cysts, 625
 Thyroglossal cysts, 626

Cystic lesions of the jaws are common pathologic lesions. This group of lesions is comprised of a number of different conditions either odontogenic or non-odontogenic in origin.

Odontogenic cysts are the most frequent, and of these the radicular cyst is seen most often. Odontogenic cysts arise from the epithelial remnants of tooth for-

mation, and consequently they are epithelially lined and develop in the tooth-bearing areas of the jaws. These lesions are benign, but very rare instances of associated malignancy or malignant change in the cyst wall are found in the literature.

Non-odontogenic cysts were classically thought to arise from epithelial remnants from the fusion of the maxillary and frontonasal processes and mandibular processes in the embryo. Aneurysmal and solitary bone cysts, however, are non-epithelial lined non-odontogenic cysts. These theories have, however, been challenged and most are now felt to be odontogenic or respiratory in origin.

Many of these lesions are slow growing and asymptomatic, often found as incidental findings at dental check-ups or with the use of panoramic radiographs for dental assessment. Accurate diagnosis and appropriate treatment are required, as these lesions will generally continue to grow and may affect adjacent teeth and other structures and even result in pathologic fracture.

The small group of developmental soft tissue cysts will be considered at the end of this chapter.

Odontogenic cysts

Apical or radicular cysts

Radicular cysts are the commonest jaw cysts, comprising half to two-thirds of all such lesions. The cyst is most commonly found associated with the apex of a tooth, but lateral periodontal cysts may be found associated with lateral canals and residual cysts persist and enlarge following extraction of the causative tooth leaving cystic remnants behind. The cyst usually arises following the development of periapical granuloma from the necrotic remnants of the dental pulp. Chronic inflammation of this tissue initially stimulates the cell rests of Malassez, resulting in epithelial proliferation. This initiation phase is then followed by a phase of cyst development, followed by cyst growth. Radicular cysts are fluid-filled lesions

that expand in the jaw by osmotic pressure and cytokines cause local resorption of bone.

Radicular cysts are uncommon in children, and become more frequent in adolescents but are most often seen in adults of all age groups. They are reported to be more prevalent in men than women, although this may be due to women taking greater care of their teeth and visiting the dentist more often than men. The maxilla is more commonly involved than the mandible. Most radicular cysts present as slow-growing, painless swellings associated with a non-vital or root-treated tooth or as incidental findings on panoramic radiographs. Less frequently, radicular cysts become infected and present as a facial abscess or cellulitis.

At presentation the oral soft tissues are often normal, but careful examination may reveal a firm, hard, smooth swelling at the apex of the tooth. As the cyst enlarges the overlying bone may become resorbed leaving a soft swelling or even a thin layer of bone that may be felt to give way on palpation (egg shell crackling). As the cyst is palpated the patient may report pain. The causative tooth will be found to be non-vital and other teeth involved as the cyst enlarges may also become devitalized.

Investigation is by vitality testing of the associated teeth and periapical or panoramic radiographs. The radiographic features are of a smooth, rounded, unilocular radiolucency with a radiopaque outline associated with the apex of a non-vital tooth. Adjacent structures may be displaced by the expanding cyst (Fig. 31.1).

Treatment is by removal of the cause of the inflammation either by extirpation of non-vital dental pulp by orthograde root filling in the first instance or by extraction of the causative tooth. Small cysts are reported to regress, however larger lesions will require enucleation, complete removal of the cyst lining usually facilitated by using a curette. In teeth previously root treated with a good periapical seal, or those restored with a post crown where the post is large and threatens root fracture if an attempt is made

Fig. 31.1 Radicular cyst arising from non-vital roots of lower left first molar tooth. Note displacement of inferior dental canal by cyst posteriorly.

to remove it, apicectomy needs to be performed if the tooth is not extracted.

Following enucleation, the soft tissue overlying the bony cavity is closed and the resulting hematoma ossifies. Some surgeons prefer to fill large cavities with corticocancellous bone chips to accelerate bone regeneration, but there are no studies to show that this practice has benefit. More recently the use of bone morphogenic protein has been described to improve rates of bone regeneration. In mandibular lesions where removal of the cyst threatens to cause a postoperative pathologic fracture, miniplates can be placed prior to closure to strengthen the weakened area of jaw. Patients with very large lesions and those who are severely medically compromised and unable to withstand a prolonged oral surgical procedure may be best treated by marsupialization (decompression) of the cyst allowing bony regeneration. The cyst is decompressed and the lining sutured to the oral mucosa. The cyst cavity should gradually regress, but the neck of the cyst needs to be held open using a pack or a bung. This process is often slow, taking many months for resolution of the cyst, and a further procedure may be required to remove the residual lining.

Residual cysts

Residual cysts develop from residual periapical infection or from cyst fragments left following extraction of a non-vital tooth. They present with similar features to the radicular cyst and radiographically are found as isolated, circumscribed, unilocular radiolucent lesions in the alveolar process but without an obvious causative tooth (Fig. 31.2). They require enucleation or marsupialization as above.

Lateral periodontal cysts

These lesions are usually asymptomatic and identified radiographically between the roots of teeth often in the mandibular canine and premolar area. The adjacent teeth are vital and the cysts are thought to arise from the cell rests within the periodontal ligament. The botyroid odontogenic cyst and glandular odontogenic cyst are variants of the lateral periodontal cyst and are both uncommon. Botyroid odontogenic cyst is found in adults of 50 years and older,

Fig. 31.2 Residual cyst from lower second premolar.

and involves the bicuspid area of the mandible. The glandular odontogenic cyst may be multilocular and is reported to be prone to recurrence. Treatment is usually by enucleation, although on occasion extraction of the involved tooth may be required.

Dentigerous cysts

Dentigerous or follicular cysts account for approximately one sixth of dental cysts. They are a fluid-filled expansion of the dental follicle and are attached to the crown of the tooth at the cemento-enamel junction.

Fig. 31.3 Dentigerous cyst arising from lower left third molar. Note displacement of the tooth and the inferior dental canal by the enlarging cyst.

As the cyst expands it prevents the eruption of the tooth and may even displace the tooth into the jaw. The most commonly involved teeth are reported to be the mandibular third molar and maxillary canine.

Dentigerous cysts are more common in men than women and usually these cysts present as an asymptomatic swelling, found when non-eruption of a tooth is investigated or incidentally with panoramic survey radiographs. Infection is uncommon, but it may present as a dentoalveolar or facial abscess.

Radiographically, a circumscribed, unilocular, radiolucent area is seen with a thin radiopaque lamina dura associated with the crown of the involved tooth. The tooth and adjacent structures may be displaced (Fig. 31.3). Cysts within the maxilla may occupy the maxillary sinus (Fig. 31.4).

Treatment is by removal of the causative tooth and enucleation of the cyst lining and the cavity is managed as described for radicular cysts. In those with very large cysts who are infirm, marsupialization may be the treatment of choice. If the tooth is to be retained for orthodontic reasons, it may also be advantageous to marsupialize the cyst.

Eruption cyst

This soft cystic swelling, usually blue or purple in color, is seen in children. It is found on the alveolus overlying an erupting tooth. The cyst most likely arises from the enamel organ. They are uncommon

Fig. 31.4 Dentigerous cyst of maxilla involving maxillary sinus: occipitomeatal radiograph and MRI.

and many burst spontaneously. Should the cyst not resolve quickly, the overlying tissue may need to be removed to allow the tooth to erupt. Radiographs are usually unnecessary, but if taken may show a lucent lesion at the alveolar margin in association with the crown of the tooth.

Gingival cysts

Two varieties of gingival cyst are found. In newborns small nodules are frequently seen on the alveolar crest. These lesions arise from proliferation of the cell rests of Serres. In the majority of cases they resolve spontaneously but persistent lesions may require local excision or curettage. In adults, usually in the fifth decade, soft tissue cysts can occasionally be found overlying the alveolus. These may cause local resorption of bone resulting in small saucer-shaped depressions in the alveolar plate. These cysts are treated by local excision.

Odontogenic keratocyst (primordial cyst, keratocystic odontogenic tumor)

The World Health Organization reclassified the odontogenic keratocyst as a benign tumor with the new title of keratocystic odontogenic tumor in 2006. It is discussed under this title in Chapter 32.

Calcifying epithelial odontogenic cyst

This rare cyst, first described by Gorlin *et al.* in 1962, may be found at any age and in either gender. It may be intraosseous or be found within the gingiva eroding the jaw. The radiographic appearance may have little calcification within it in early lesions, giving a similar appearance to other jaw cysts, but with increasing calcification may have the appearance of an odontome or calcifying odontogenic tumor. It has a benign behavior but can be aggressive and recur. Initial treatment is usually by enucleation and curettage.

Malignancy within odontogenic cysts

This is very rare but a few cases are reported of malignancy in the wall of dental cysts. Such lesions should be managed as primary malignant tumors once the diagnosis is established.

Non-odontogenic cysts

Fissural cysts

Fissural cysts were originally described to classify cystic lesions found in areas of what were believed to

be embryonic fusion. With more detailed studies these lines of fusion are believed not to exist and close examination of previous cases shows that most of these cysts actually have an odontogenic cause. However, the names are occasionally used for descriptive purposes only.

Globulomaxillary cysts

The term globulomaxillary cyst is an umbrella term used for cystic lesions appearing between the upper lateral incisor and canine tooth. It was originally felt to arise from epithelium due to embryonic fusion of the maxillary process with the nasal process, but this version of embryonic fusion has no supporting evidence. Many reported cases are in fact apical cysts related to non-vital lateral incisors or other cystic lesions. Treatment is by enucleation.

Median mandibular cyst

This is a term for cystic lesions in the midline of the jaw. Original proposals for this being of embryonic origin have now been disproved and, rather like the globulomaxillary cyst, most cases are in fact of odontogenic origin.

Nasopalatine cysts

Nasopalatine or incisive canal cysts arise from the epithelial remnants of the embryonic nasopalatine ducts. This occurs during the creation of the incisive canal by the fusion of the premaxilla with the palatine processes of the maxillary bones. The etiology of cyst formation may be local inflammatory processes such as infection and trauma. Nasopalatine cysts are more common in males than females and in the fourth to sixth decades. The cyst presents as a symmetrical swelling behind the upper incisors in the midline. Rarely, a fistula can be found leading to the incisive canal. Radiographs show a midline round or oval radiolucent lesion which may displace the roots of the central incisors laterally (Fig. 31.5). Accurate vitality tests are essential to avoid misdiagnosis. It is difficult to differentiate a small nasopalatine cyst from a large incisive canal, but it has been proposed that an

Fig. 31.5 Nasopalatine cyst.

incisive canal of less than 6mm on occlusal radiograph is within normal limits provided the patient has no symptoms nor abnormal clinical findings. Treatment is by enucleation.

Non-epithelially lined cysts

Stafne/static bone cyst

This classic radiolucency is found in the mandible as an incidental finding on survey radiographs such as orthopantomograms and lateral obliques. A small, smooth outlined lesion is found beneath the second and third molar teeth and below the inferior dental canal. The lesion is asymptomatic and is not a true cyst. It is an invagination of the medial aspect of the mandible usually containing salivary tissue, although lymphoid tissue has been reported. Occasional cases are reported of Stafne-type lesions occurring more anteriorly in the mandible. In difficult cases radiographic assessment can be made with either fine cut coronal computed tomography (CT) scan to determine the bony anatomy and the soft tissue signal within the cavity or by magnetic resonance imaging (MRI) scan. Biopsy and exploration are not indicated.

Aneurysmal bone cysts

This non-epithelially lined cyst-like lesion occurs occasionally in the jaws. It is more common in the mandible than maxilla. The etiology is unknown, but essentially it is a vascular malformation that arises from a prior unrelated lesion. It presents in adolescents and young adults as a swelling, which is painful in 50% of cases, or as an incidental finding on a panoramic radiograph. Radiographically it may be a uni- or multilocular lesion with irregular outline and occasional displacement of tooth roots. Histopathologically, the lesion contains many giant cells and can be indistinguishable from central giant cell granuloma. This feature has led to the idea that aneurysmal bone cysts are a vascular variation of central giant cell granuloma. Treatment is by curettage although the lesions can recur. Resection and adjuvant cryotherapy have been proposed for large or recurrent lesions.

Solitary bone cyst

Solitary bone cysts have been given many titles including simple bone cyst, traumatic bone cyst, hemorrhagic bone cyst, and latent bone cavity. All these terms refer to the same lesion, a non-epithelially lined space that may be found to contain a small amount of straw-colored fluid but may have no fluid within it. It is found most often in the long bones and rarely in the jaws. Its etiology is unknown, but trauma has been proposed, following which there is intramedullary bleeding and clot formation. However,

instead of the normal process of resorption of the clot and bone formation, the clot liquefies leaving a cavity. It is then proposed that the liquid content decreases with time and the lesion becomes filled with gas. The oxygen from this is absorbed into the blood leaving nitrogen that has been found on analysis. It is most commonly found in adolescents as a painless swelling or incidental finding on radiographs affecting the mandible. Females are more commonly affected than males (3:2). It has rarely been described in association with florid cemento-osseous dysplasia. Radiographs show a radiolucency that extends between the roots of involved teeth. One explanation for their rare appearance after adolescence is that these lesions spontaneously resolve. In longstanding or large lesions treatment is by curettage of the cavity, which results in clot formation and complete bony infill.

Soft tissue cysts

Nasolabial cysts

This is a rare cyst of the soft tissues with unknown etiology. Like the globulomaxillary cyst it has been proposed to arise from embryonal fusion but this has no evidence to support it. This cyst is commonest in the fourth and fifth decades and is more common in females (male:female 1:4). It is found as a swelling at the nasal fold and can become quite large before being detected causing distortion of the alar rim and local resorption of the maxilla. Treatment is by excision. It can be lined by squamous or respiratory epithelium.

Sublingual dermoid and dermoid cysts

Sublingual dermoid cysts are soft tissue cysts found in the midline beneath the tongue and as far down as the hyoid bone. These cysts are believed to arise from epidermal cell rests resulting from the fusion of embryonal processes. Unlike mucous retention cysts they are deeply placed and filled with keratin, giving a much firmer feel. Initially they are asymptomatic but as they increase in size they start to affect speech and swallowing if above the mylohyoid, where they bulge into the floor of the mouth. Those cysts arising below mylohyoid appear as a swelling in the neck. Treatment is by excision.

Other small dermoid cysts may be found within the skin of the head and neck and implantation dermoid cysts can arise from local trauma where skin is driven into the subepithelial layers. These lesions are treated by surgical excision.

Branchial lymphoepithelial cysts

Branchial cysts arise from incomplete obliteration of branchial clefts or epithelial inclusions within lymph

Fig. 31.6 Branchial cyst: axial and coronal MRI views showing cyst deep to sternomastoid.

nodes. Lymphoepithelial cysts are found in the floor of the mouth and posterior tongue. Branchial cysts usually present as asymptomatic swellings in the lateral aspect of the neck at the anterior border to the sternomastoid. Rarely, they present with acute infection. Branchial cysts are commonest in children and young adults, but can occur in older patients. In those over 40 years, cysts presenting in this fashion should be investigated for tonsillar or tongue base carcinoma as cystic metastasis for such lesions is the commonest cause of lateral neck cysts in this age group. Rare cases of primary branchial cyst carcinoma are reported in the literature.

In those with simple branchial cyst the neck should be imaged with MRI scan (Fig. 31.6) and the cyst excised. Any track to the pharynx should also be excised.

Thyroglossal cysts

These cysts arise from the thyroglossal duct, which should break down following the migration of the thyroid gland from the foramen caecum in utero. These cysts present as midline swellings anywhere from the tongue base to the thyroid gland. They are usually asymptomatic. Due to the attachment of the tract to the hyoid bone and the tongue, the cysts move on swallowing and protrusion of the tongue. Investigation is by MRI scan and fine-needle aspiration. Thyroid scans will occasionally show these cysts to be active, but usually patients have adequate other functioning tissue. Solid lesions may, however, represent all of the patient's functioning thyroid tissue and a thyroid scan is required before the removal of such a lesion. Cases of carcinoma within thyroglossal cysts are reported. Treatment for uncomplicated thyroglossal cyst is by the Sistrunk procedure, which involves excision of the cyst and the central portion of the hyoid bone.

Chapter 32

Odontogenic and Non-odontogenic Tumors of the Jaws

R. Bryan Bell

This chapter will cover the classification, frequency of occurrence, etiology, molecular biology, histogenesis, treatment, and prognosis for odontogenic and non-odontogenic tumors:

- Benign epithelial odontogenic tumors include ameloblastomas, keratocystic odontogenic tumors, calcifying epithelial odontogenic tumors, and adenomatoid odontogenic tumors.
- Benign mixed odontogenic tumors include ameloblastic fibroma, ameloblastic fibro-odontoma, odontomas, odontoameloblastomas, calcifying cystic odontogenic tumors, and dentinogenic ghost cell tumors.
- Mesenchymal odontogenic tumors include odontogenic fibromas, odontogenic myxomas, and cemento-blastomas.
- Non-odontogenic tumors include the ossifying fibroma, fibrous dysplasia, osseous dysplasia, giant cell lesions, and simple bone cysts.
- Malignant odontogenic tumors include the ameloblastic carcinoma, primary interosseous squamous cell carcinoma, clear cell odontogenic carcinoma, ghost cell odontogenic carcinoma, and odontogenic sarcomas.
- Non-odontogenic malignant tumors include osteosarcoma, chondrosarcoma, Ewing sarcoma, malignant peripheral nerve cell tumors, and metastatic tumors.

Introduction

Odontogenic and non-odontogenic tumors of the jaws are a relatively rare and heterogeneous group of

benign and malignant neoplasms, hamartomas, and other bone-related lesions that demonstrate great variability in etiology, biologic behavior, and clinical significance. The single commonality amongst these

cellular proliferations is that they may occur in the jaws. Odontogenic tumors, by definition, are derived from tooth-related tissues and, although they have been reported in tooth-bearing structures such as dermoid cysts and teratomas, originate only in the maxilla or mandible. The majority of these disorders are benign, and while they may be locally aggressive, only very rarely do they have the ability to metastasize. Non-odontogenic jaw tumors, on the other hand, develop from the epithelium and/or mesenchyme of a wide variety of tissues in the body, often originate in non-tooth-bearing facial bones, and may develop in other sites outside of the head and neck. Some of these are of little clinical significance and require nothing more than observation or local excision, while many of the malignant variants mandate multimodal therapy and portend a poor prognosis for survival.

Odontogenic tumors

Odontogenic tumors (OT) are derived from tooth-forming elements and for the purposes of this chapter include lesions that are not definitively neoplastic. Even using this broad definition, OTs are rare lesions that account for <2–3% of all oral and maxillofacial specimens sent for diagnosis to oral pathology services.¹ It has been estimated that if viewed as a percentage of all tumors in the human body, this figure may only be 0.002–0.003%.²

Odontogenesis occurs through a complex process involving the enamel organ, the dental follicle, and the dental papilla (Fig. 32.1). The enamel organ is an epithelial structure that is derived from oral ectoderm. The dental follicle and dental papilla are derived from neural crest cells and are therefore considered ectomesenchymal in nature. Odontogenic tumors demonstrate varying inductive interactions between the odontogenic epithelium and odontogenic ectomesenchyme and are typically subclassified by their tissue of origin.

Classification

The first significant attempt to classify odontogenic tumors probably occurred in 1869 when the French physician and professor of pathology and clinical surgery, Pierre Paul Broca,³ suggested that tumors arising from the dental formative tissues (he termed them odontomes) were organized according to the stage of development of the tooth when abnormal growth commenced. Later modified by Malassez in 1885,⁴ neither of these classification schemes gained much traction in the international scientific community. In 1888, Bland-Sutton⁵ provided what might be considered the foundation for our current system of taxonomy by basing his classification on the particular cells of tooth germ from which the tumor arose. Gabell, James, and Payne⁶ further modified Bland-Sutton’s classification by recognizing three distinct groups of odontomes: epithelial, composite, and connective tissue. In the years to follow, the term odontome was gradually replaced by terms more compatible with general pathological use.⁷

In 1946 Thoma and Goldman⁸ described our modern classification of odontogenic tumors based on the tissue cell of origin using contemporary terminology. Subsequently revised by Pindborg and Clausen⁹ and Gorlin and colleagues,¹⁰ these classifications provided a structured means to catalog and study lesions but did not provide the clinician with a useful guide to clinical decision making. In 1971, under the leadership of Pindborg and Kramer, the World Health Organization¹¹ (WHO) published a classification that distinguished between lesions and tumors of the odontogenic apparatus, neoplasms and other lesions of bone. Furthermore, it subclassified these disorders according to their biologic behavior as being benign or malignant. The WHO classification was revised in 1992 by Kramer, Pindborg, and Shear¹² as a reflection of increased knowledge of the origin and inductive interaction of odontogenic tissues, but almost immediately evoked persistent criticism.^{13–15}

A better understanding of the pathogenesis and progression of odontogenic tumors is currently being developed as a result of chromosomal and molecular genetic analyses. Ultimately, this information can be used to better predict the biologic behavior of a particular tumor, properly select the appropriate treatment, and develop novel forms of therapy directed against specific genetic alterations. Such studies are underway for various odontogenic cysts and tumors that, in part, led Philipsen and Reichart in 2002¹⁶ to suggest another classification change.

The new WHO classification of odontogenic tumors was published in July 2005 (Table 32.1)¹⁷ and made a number of important changes to terminology, benign or malignant classifications, and assignment to relevant subgroups.¹⁸ Previous WHO classifications described only tumor histology. The new publication includes other information such as definition,

MALIGNANT TUMORS
Odontogenic carcinomas
Metastasizing (malignant) ameloblastoma
Ameloblastic carcinoma – primary type
Ameloblastic carcinoma – secondary type (dedifferentiated), intraosseous
Ameloblastic carcinoma – secondary type (dedifferentiated), peripheral
Primary intraosseous squamous cell carcinoma-solid type
Primary intraosseous squamous cell carcinoma derived from keratocystic odontogenic tumor
Primary intraosseous squamous cell carcinoma derived from odontogenic cysts
Clear cell odontogenic carcinoma
Ghost cell odontogenic carcinoma
Odontogenic sarcomas
Ameloblastic fibrosarcoma
Ameloblastic fibrodentino- and fibro-odontosarcoma
BENIGN TUMORS
Odontogenic epithelium with mature, fibrous stroma without odontogenic ectomesenchyme
Ameloblastoma, solid/multicystic type
Ameloblastoma, extraosseous/peripheral type
Ameloblastoma, desmoplastic type
Ameloblastoma, unicystic type
Squamous odontogenic tumor
Calcifying epithelial odontogenic tumors
Adenomatoid odontogenic tumor
Keratocystic odontogenic tumor
Odontogenic epithelium with odontogenic ectomesenchyme, with or without hard tissue formation
Ameloblastic fibroma
Ameloblastic fibrodentinoma
Ameloblastic fibro-odontoma
Odontoma, complex type
Odontoma, compound type
Odontoameloblastoma
Calcifying cystic odontogenic tumor
Dentinogenic ghost cell tumor
Mesenchyme and/or odontogenic ectomesenchyme with or without odontogenic epithelium
Odontogenic fibroma
Odontogenic myxoma/myxofibroma
Cementoblastoma
Bone-related lesions
Ossifying fibroma
Fibrous dysplasia
Osseous dysplasias
Central giant cell lesion (granuloma)
Cherubism
Aneurysmal bone cyst
Simple bone cyst

epidemiology, etiology, localization, clinical and imaging features, macroscopy, histopathology, tumor genetics, and prognosis.

Odontogenic cysts were not considered in the new 2005 classification, which means that the 1992 classification is still relevant for cysts of the jaws and maxillofacial region, with one notable exception: the odontogenic keratocyst (OKC) was renamed “keratocystic odontogenic tumor” (KOT) and was added to the odontogenic tumors category. The change in terminology is a reflection of contemporary clinical, molecular, and immunohistochemical data suggesting that the KOT is a benign neoplasm rather than a cyst. The nevoid basal cell carcinoma syndrome (NBCCS) or PTCH-gene has been mapped to chromosome 9q23.3-31 where it probably acts as a tumor suppressor.¹⁹ A two-hit mechanism in the pathogenesis of NBCCS and sporadic KOT demonstrated allelic loss of 9q22 with overexpression of bcl-1 and TP53 in NBCCS.²⁰ There is also evidence suggesting that the PTCH-gene is a significant factor in the development of sporadic KOT. Evolving research demonstrates that the loss of tumor suppressor genes may play an important role in the aggressive clinical behavior of KOTs, provides a partial explanation for their propensity to recur after conservative treatment, and supports the view that KOTs are indeed benign neoplasms.²¹⁻²³

Another important change in the 2005 WHO classification is related to malignant tumors of odontogenic origin. The metastasizing ameloblastoma was incorrectly described in the 1992 classification. It is now clarified in the 2005 document, which provides a clear distinction between the metastasizing ameloblastoma (containing benign histological features) and ameloblastic carcinoma. The diagnosis of an ameloblastic carcinoma is made in the presence of malignant histological features. In addition, the clear cell odontogenic carcinoma (CCOC), formerly clear cell odontogenic tumor, has been added to the list of malignant odontogenic carcinomas due to its newly recognized aggressive behavior.

The 2005 classification also recognizes the existence of variants, by using the plural term: ameloblastomas. Four ameloblastoma variants are now recognized: (1) solid/multicystic ameloblastoma; (2) extraosseous/peripheral ameloblastoma; (3) desmoplastic ameloblastoma; and (4) unicystic ameloblastoma. The demographics, clinical features, and biologic behavior of each of these entities are variable and probably contribute to the lack of consensus regarding optimal treatment.

The adenomatoid odontogenic tumor was formerly grouped with the “mixed odontogenic tumors” and has now been added to the benign tumors category with odontogenic epithelium and mature stroma without odontogenic ectomesenchyme.

The calcifying cystic odontogenic tumor is described with synonyms such as calcifying odontogenic cyst, Gorlin cyst, and calcifying odontogenic

tumor. Although there is no consensus regarding the continued separation of the cystic variants, it is possible that future revisions will lump this entity into a single term.

Two variants of the central odontogenic fibroma were described in the 1992 classification that is now termed “epithelial-poor” and “epithelial-rich”, based on histological findings.

The term “osseous dysplasias” has now been introduced which pools groups of bone-related lesions under one heading. The former terms of cementifying ossifying fibroma and cementifying osseous dysplasias have been changed to ossifying fibroma and osseous dysplasia respectively.

The genetic basis of head and neck tumors is complex, and knowledge of the mechanisms that drive neoplastic growth and development is in its infancy. As a result of chromosomal and molecular genetic analyses, a better understanding of the pathogenesis and progression of odontogenic tumors is being developed and will, no doubt, lead to future changes in the classification of these diverse cellular proliferations.

Molecular biology

Various genetic and molecular alterations appear to promote the development and progression of tumors via a series of complex processes. Recent studies have identified a number of molecular alterations that are responsible for the development and progression of odontogenic tumors and may provide further insight into their etiology, pathogenesis, and treatment (Table 32.2).²⁴

Oncogenes are normal cellular genes that contribute to neoplastic transformation through functions activated by gene amplification, translocation, or mutation. Many oncogenes have been described. Among other things, these oncogenes appear to function as growth factors, such as platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF); growth factor receptors, such as epidermal growth factor receptor (EGFR), HER-2, and Ret; non-receptor tyrosine kinases (Src, Abl); serine/threonine kinases (Mos); signal transducers (Ras); and transcription factors (Myc, Fos). Ameloblastomas have been shown to be EGFR positive. Products encoded by Ras genes (p21Ras) have been shown to be preferentially expressed in the odontogenic epithelium of ameloblastomas, ameloblastic fibromas, and odontogenic myxomas.^{25,26} C-Myc oncoprotein is expressed predominantly in neoplastic cells neighboring the basement membrane of ameloblastomas.²⁷ Fos oncogene encodes a transcription factor participating in the control of cell proliferation and differentiation in ameloblastomas on cDNA microarray and subsequent real-time reverse transcriptase polymerase chain reaction, suggesting that these oncogenes play a role in the pathogenesis of odontogenic tumors via dysregulation of cell proliferation.²⁸

Table 32.2 Summary of molecules involved in the development and progression of odontogenic tumors. Adapted from Kumamoto M. Molecular pathology of odontogenic tumors. *J Oral Pathol Med* 2006; 35: 65–74.

Molecules possibly associated with tumorigenesis and/or tumor cell differentiation	
Oncogenes	<i>Ras, Myc, Fos</i>
Tumor-suppressor genes	<i>p53, APC</i>
Oncoviruses	HPV, EBV
Growth factors	TGF- α , - β , FGF-1, -2, HGF
Telomerase	Telomerase
Cell cycle regulators	Cyclin D1, P16 ^{INK4a} , p21 ^{WAF1/Cip1} , p27 ^{Kip1}
Apoptosis-related factors	Bcl-2 family, IAP family, Fas, TNF- α , p53
Regulators of tooth development	SHH pathway, Wnt pathway
Hard tissue-related proteins	Amdogenin, enamelin, ameloblastin, enamelysin, BSP, osteonectin, osteocalcin, osteopontin, BMP
Molecules possibly associated with tumor progression	
Cell adhesion molecules	E-selectin, ICAM-I, VCAM-I, E-cadherin, integrins, CD44
Matrix-degrading proteinases	MMP-I, -2, -9/IMP-I, -2, heparanase
Angiogenic factors	VEGF
Osteolytic cytokines	IL-I, -6, TNF- α , PTHrP, RANKL/OPG

HPV, human papilloma virus; EBV, Epstein–Barr virus; TGF, transforming growth factor; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; IAP, inhibitor of apoptosis protein; TNF, tumor necrosis factor; SHH, Sonic hedgehog; BSP, bone sialoprotein; BMP, bone morphogenetic protein; ICAM, intercellular adhesion molecule; VCAM, vascular cell adhesion molecule; MMP, matrix metalloproteinase; TIMP, tissue inhibitor of metalloproteinases; VEGF, vascular endothelial growth factor; IL, interleukin; PTHrP, parathyroid hormone-related protein; RANKL, receptor activator of nuclear factor-KB ligand; OPG, osteoprotegerin.

Tumor-suppressor genes act as regulators of cell growth. Inactivation of these genes by mutations and/or loss of heterozygosity in both alleles results in tumor development. p53 gene is the most well studied, however other genes have been identified including retinoblastoma (RB), adenomatous polyposis coli (APC), ST-1, and patched (PTC) genes. Although several studies have shown p53, mutations are infrequent in benign ameloblastomas,^{29–31} p53 reactivity has been detected in ameloblastomas, malignant ameloblastomas, primary introsseous carcinomas, and ameloblastic fibrosarcomas.^{32–35} Furthermore, there is some evidence that hypermethylation of p16 may be involved in the malignant transformation of ameloblastoma.³⁶ More recent studies have demonstrated high levels of Ki-67, p53 and p63 in KOTs, thus favoring its tumorigenesis.^{37,38} Immunohistochemical reactivity for APC is lower in benign and malignant ameloblastomas than in tooth germs.³⁹ Although RB has not been investigated in odontogenic tumors, there is evidence to suggest an association between tumor-suppressor genes and the development of odontogenic tumors via aberrant control of cell proliferation.⁴⁰

A comprehensive review of the molecular biology of odontogenic tumors is well beyond the scope of this chapter. The reader is referred to other, more definitive reviews of the subject.²⁴ Suffice it to say, the characteristics of odontogenic tumors appear to depend on the molecular mechanisms associated with tooth development, bone metabolism, and the malignant potential of tumors. Future molecular studies are underway that are investigating the

genomic- and proteomic-based profiling that will hopefully lead to the development of new therapeutic modalities.

Treatment options for benign tumors of the jaws

Enucleation and curettage

Enucleation and curettage has been the traditional and time-honored method for managing odontogenic cysts and some jaw tumors. The technique offers the patient a minimally invasive procedure, with little associated morbidity and few complications. Most odontogenic cysts can be effectively removed by simple enucleation of the cystic lining and meticulous curettage of the bony cavity. However when used alone, this technique is usually inadequate for tumors with true neoplastic potential and its use in entities such as ameloblastoma or keratinizing odontogenic tumor should be accompanied by adjuvant treatment, such as peripheral osteotomy, cryotherapy, or chemical fixation with Carnoy's solution.

Wide exposure is necessary to allow complete access to the bony cavity (Fig. 32.2a). Every effort must be made to thoroughly remove the cyst lining as well as epithelial remnants that may be present between the cyst wall and overlying mucosa. One of the difficulties encountered when attempting to remove these cysts lies in the nature of the thin cystic lining which, at times, is readily removed *in toto*, but more often comes out in multiple soft tissue

Fig. 32.2 Enucleation and curettage. (a) Exposure of the cyst to allow complete access to the bony cavity. (b) Complete, intact removal of the cyst. (c) Complete, fragmented removal of the cyst.

fragments (Fig. 32.2b, c). The inferior alveolar nerve can be routinely spared and root canal therapy is almost never indicated. Most of the time, the mucosa can be closed primarily, without the need for bone grafts or packing material. Removal of a large cyst will occasionally weaken the remaining bony integrity, placing it at risk for pathologic fracture. This can be managed with 6 weeks of intermaxillary fixation and/or placement of a reconstruction plate. Enucleation and curettage is a reasonable method for the primary treatment of small, unilocular cysts that are typically not biopsied prior to definitive treatment.

Enucleation and peripheral osteotomy

Enucleation with peripheral osteotomy is an extension of the curettage technique described above. It involves the use of a rotary instrument to remove bone adjacent to the cystic lining, theoretically facilitating removal of all residual epithelium and/or daughter cysts (Fig. 32.3). Some authors have described the use of methylene blue to aid in identification of appropriate bony margins.⁴¹ The technique can stand alone or include chemical or thermal fixation of the interior of the bony cavity. The advantage of peripheral osteotomy is that it provides an additional “margin” of bone removal during excision of the lesion and can potentially alleviate the need for adjunctive measures. The disadvantages are that it places other anatomic structures at risk of injury, i.e. teeth and the inferior alveolar nerve, and may further weaken the jaw structure. There are only limited published data comparing this technique with other tech-

Fig. 32.3 Illustration of peripheral osteotomy.

niques, with or without chemical or thermal fixation, therefore recurrence rates for treatment of odontogenic tumors are not truly known. However, the use of peripheral osteotomy for treatment of a number of odontogenic tumors has merit in that it can facilitate a more “radical” surgery than curettage but is less morbid than resection.

Marsupialization

Marsupialization is a technique advocated by some authors that is designed to initially decompress and shrink the cyst or tumor prior to definitive removal, generally by enucleation and curettage several months later. The primary advantage of this method is to minimize the surgical defect that is created by removal of the cystic lesion. This technique has been observed to cause inflammation and subsequent thickening of the cystic lining which facilitates its ultimate removal. Various inflammatory mediators may play a role in cyst volume reduction. Recently,

marsupialization was shown to inhibit interleukin-1alpha expression within the lining of KOTs, thereby halting epithelial cell proliferation and decreasing the size of the cystic tumor.⁴² The technique is performed by “de-roofing” the cyst and either repeatedly packing the cavity with gauze or by simply placing a tube, catheter or drain in order to facilitate gradual decompression and shrinkage of the defect. The pack or drain is left in place for 2–3 months, depending on the size of the lesion, and is followed by an enucleation procedure.

Technique

The author favors removal of overlying bone and cyst roof, creating an opening into the cyst that is as wide as possible. A 1" (2.5cm) Penrose drain is cut to a length just long enough to reach the depth of the lesion. Its periphery is sutured to the gingival and alveolar mucosa around the defect with approximately eight 2-0 silk sutures (Fig. 32.4). The patient is instructed in wound irrigation with saline and the drain is allowed to spontaneously exfoliate, which usually occurs within 1–2 months. In cases of extensive mandibular destruction, an ipsilateral coronoidectomy may help avoid pathologic fracture.

Intralesional adjunctive therapy: chemical fixation

Remnants of the dental lamina have been hypothesized to play a role in the etiology of some odontogenic tumors.⁴³ The presence of epithelial islands within the mucosa overlying the cyst as well as the bony cavity has prompted the use of various surgical strategies to adjunctively treat the surrounding tissue in an effort to eradicate residual disease and minimize recurrence. The use of such adjuvant measures is perhaps best studied in the treatment of KOTs. Stoelinga, Voorsmit, and their colleagues from Denmark advocate excision of the overlying mucosa and have popularized the use of Carnoy’s solution as a chemical tissue fixative for treatment of KOTs.^{44–47} Carnoy’s

Fig. 32.4 Marsupialization of a keratinizing odontogenic tumor (KOT).

Table 32.3 Carnoy’s solution (Cutler and Zollinger).

Absolute alcohol	6ml
Chloroform	3ml
Glacial acetic acid	1ml
Ferric chloride	1g

solution is a mixture of absolute alcohol, chloroform, glacial acetic acid, and ferric chloride that penetrates bone to a predictable, time-dependent depth, without injuring the neurovascular structures (Table 32.3). A 5-minute application will penetrate bone to a depth of 1.54mm, nerve to a depth of 0.15mm and mucosa to a depth of 0.51mm (Table 32.4).⁴⁶ Because most residual cells and daughter cysts from locally recurrent lesions are adjacent to the main lesion, it is likely that fixation of vital bone need only extend for 2–3mm beyond the enucleated lesion. Theoretically, enucleation of the cyst wall, excision of the overlying mucosa, and treatment of the surrounding tissue with Carnoy’s solution should sufficiently remove the cystic lesion along with any epithelial remnants remaining in the area. Application of the Carnoy’s solution can be either prior to enucleation or afterwards. Voorsmit’s original description of the technique called for treatment of the cyst before enucleation which causes a “tanning effect” of the lesion thereby facilitating complete removal. The author’s experience, however, is that treatment of the bony cavity after enucleation allows for easier removal of the cyst lining and better identification of soft tissue remnants. There is no evidence in the literature to support one method being superior to the other. Furthermore, there is nothing to suggest that coating the neurovascular bundle with petroleum jelly or the like affects neurosensory outcome.

Technique

Following cyst enucleation through a generous access window and a peripheral osteotomy, the defect is filled with ¼" (6mm) or ½" (12mm) ribbon gauze (Fig. 32.5). Care is taken to protect the surrounding soft tissues with gauze sponges or towels (Fig. 32.6). A syringe and angiocath are used to administer the Carnoy’s solution, soaking the gauze thoroughly. After a period of 5 minutes the gauze mass is clamped with forceps and is manipulated within the cavity to ensure complete application to all walls. The gauze is then removed and the cavity irrigated with copious amounts of saline solution. Primary closure is achieved and strong consideration is made to perform a primary bone graft in medium and large-sized tumors.

Intralesional adjunctive therapy: cryotherapy

Cryosurgery is a method of treating disease by the production of freezing temperatures in tissue.

Table 32.4 Carnoy's solution: depth of penetration (mm). Adapted from: Voorsmit RACA. The incredible keratocyst: a new approach to treatment. *Dtsch Zahnarztl* 1985; 40: 641–4.

Fig. 32.6 Photograph of patient with Carnoy's burn to the lip. These burns typically heal without a scar, but can be avoided with proper protection.

Cryosurgical techniques were first described in 1850, modernized in the 1960s, and revitalized in the 1990s, and they are used for tumors in diverse sites.⁴⁸ Various authors have advocated the use of cryotherapy as an adjunct to the surgical treatment of benign cysts and tumors of the jaws over the last three decades.^{49–54} Cryosurgery for osseous lesions produces cellular necrosis in bone while maintaining the inorganic osseous framework.⁵⁵ Predictable cell lysis occurs in temperatures below -20°C and is caused by direct damage from intracellular and extracellular ice crystal formation, osmotic disturbances, and electrolyte imbalance.⁵⁶ Similar to chemical fixation with Carnoy's solution, cryosurgery allows for removal of the cyst or tumor by enucleation and curettage followed by treatment of the surrounding tissue. A single 1-minute freeze produces a depth of bone necrosis of 1–3 mm depending on the technique.⁵³ The techniques acceptable for oral cryosurgical use include the cryoprobe with water-soluble jelly and liquid nitrogen spray. The advantage of a cryoprobe with jelly is that it is possible to freeze irregular, gravity-dependent portions of the bony cavity. The disadvantage is that there is non-uniform freezing. The advantage of liquid nitrogen spray is potent, uniform freezing. The disadvantage is the potential for damage to surrounding tissues. Immediate bone grafting has been recommended for defects greater than 4 cm that are treated with cryotherapy.⁵⁷ Bone grafting is thought to decrease complications such as wound dehiscence and pathologic fracture, while simultaneously providing greater residual bone height and density, thus facilitating implant placement.

Technique

The preparation for cryotherapy begins with placing the patient on a fully adjustable operating table with the patient's head on a Mayfield horseshoe head holder, in order to allow intraoperative repositioning. An aggressive removal of overlying bone and any soft tissue that might harbor cyst epithelium is per-

formed. The cyst is then removed as thoroughly as possible, although cysts extending into the condyle often defy complete removal. In anticipation of wound closure following later bone graft placement, a removal of the superior quarter of the mandibular height is performed as in a piecemeal marginal mandibulectomy. Coronoidectomy may be performed to decrease bite force and avoid pathologic fracture. Malleable retractors are positioned so as to self-retain gauze sponges to protect and insulate the soft tissues (Fig. 32.7). If a cryoprobe is to be used, a portion of the defect is filled with water-soluble jelly. The nitrous oxide cryoprobe is activated once it is immersed in

Fig. 32.7 Cryotherapy preparation. Malleable retractors are positioned so as to self-retain gauze sponges to protect and insulate the soft tissues.

Fig. 32.8 Cryo-applicator in water-soluble jelly.

Fig. 32.9 Open funnel cryo-application system.

the jelly-filled cavity (Fig. 32.8). The freeze process is continued for 2 minutes and then the ice ball is allowed to thaw. The freeze process is repeated three times. A significant limitation of the cryoprobe technique is the limited area of freezing that occurs, therefore the technique should be used on small cavities.

Alternatively, a commercially available cryospray may be used, or an even simpler open funnel system may be assembled (Fig. 32.9). The operating table is then positioned until inspection of the meniscus of a trial filling of the defect with saline demonstrates that the entire defect is flooded with saline. Larger defects and those that involve both the mandibular body and ascending ramus may require two separate positionings and treatments. Using a ladle and funnel or a commercially available applicator, the defect is then carefully filled with liquid nitrogen. Following three freeze-thaw cycles, the defect is filled with autogenous bone graft material and an everted, multiple layer closure of the overlying soft tissue is performed.

Resection

The aggressive clinical behavior of some odontogenic and non-odontogenic jaw tumors is well recognized. Although rare, extension into vital anatomic regions occurs and can involve the skull base,^{58–62} infratemporal fossa,^{63,64} and/or orbit.^{65–69} Composite, segmental or marginal resection should be considered for some large primary or recurrent benign tumors, tumors involving the orbit, posterior maxilla, pteryopalatine fossa, skull base or infratemporal fossa, and malignant tumors.

Technique

The mandible or maxilla is skeletonized in a subperiosteal or suprapariosteal plane (depending on the histological diagnosis and extraosseous tumor extension), taking care to excise periosteum that might be contaminated by tumor perforation of cortical bone. The inferior alveolar nerve can be preserved if appro-

priate, and a segmental or marginal resection performed with care to maintain 0.5–1 cm tumor-free margins. For patients with recurrent lesions, periosteum and/or mucosa is resected with bone in areas of perforation and along previous incision lines. Lesions located at the retromolar trigone can often be marginally resected using a transbuccal approach (Fig. 32.10). Following soft tissue excision of the overlying mucosa, a stab incision is made in the cheek that facilitates placement of the reciprocating saw blade. The handpiece is then attached to the saw blade and the marginal resection performed. The soft tissue and bone are removed *en bloc*. Occasionally, the residual bone volume is insufficient to allow function and may be at risk for pathologic fracture, either intraoperatively or postoperatively. These patients may benefit from reinforcement with plate fixation.

If segmental resection is to be performed, a reconstruction plate should be adapted prior to resection, if possible, or a stereolithographic model used to prebend the plate. Following resection, the decision to perform delayed non-vascularized bone graft reconstruction or immediate reconstruction with free tissue transfer should be made depending on a number of patient-related, tumor-related, and defect-related factors.

Reconstruction

Ideally, benign or malignant ablation should be followed by immediate oromandibular or palatamaxillary reconstruction to re-establish function and achieve an acceptable cosmetic result. Immediate bony reconstruction of smaller defects can be performed by using non-vascularized autogenous bone grafts harvested from the ilium. Important factors that have been found to affect graft survival include the length of the mandibular defect, timing of the reconstruction (immediate versus delayed), pre- or postoperative radiation therapy, postoperative recipient site complications, malignant diagnosis, intraoral communication, estimated blood loss, the number of days on postoperative antibiotics, and the use of soft tissue flaps (Table 32.5).⁷⁰ In the primary setting, however, microvascular transfer of free osteocutaneous flaps from the fibula, iliac crest, radial forearm, or scapula seems to provide the most reliable means for reconstruction of composite or segmental defects. More than 15 years have elapsed since the introduction of microvascular surgery to head and neck reconstruction and a number of studies with large series of patients demonstrate that in experienced hands the success rate for re-establishing mandibular continuity is greater than 95%.^{71–80}

Length of the defect has been shown to be an important factor in bone graft survival for mandibular reconstruction. Foster *et al.*⁸¹ critically evaluated the use of non-vascularized grafts compared to microvascular composite free flaps in reconstruction of mandibular continuity defects and found that suc-

cess was dependent in part on the length of the defect. Success rates in terms of osseous union using non-vascularized bone grafts decreased significantly in those patients with defects greater than 6cm. The overall success rate of non-vascularized bone grafts was approximately 69% while the overall success rate of vascularized bone flaps was 96%. Additionally, it took an average of 2.3 operations to complete the

reconstruction for those patients with non-vascularized bone grafts as opposed to only 1.1 operations for those patients with vascularized bone flaps. A follow-up study at the same institution by Pogrel *et al.*⁸² reported an increased rate of failure for continuity defects greater than 9cm and recommended that vascularized grafts be used in such cases to improve outcome (Fig. 32.11). These findings were further supported in a more recent study by August *et al.*⁷⁰ who reviewed a series of 70 cases of mandibular reconstruction performed at their institution over a 15-year period in an attempt to identify factors that affect the long-term outcome. All except two patients underwent reconstruction using corticocancellous bone grafts, occasionally combined with a sternocleidomastoid flap. Overall success, defined as wound closure, freedom from infection, bony continuity, and maintenance of bulk, was remarkably similar to that of Foster *et al.*, at 68.8%. The failure rate was highest in defects with an average length of 9.9cm, whereas the average length of successfully reconstructed defects was 7cm. For these reasons the author

Fig. 32.11 The failure rate of non-vascularized bone grafts when related to the length of the graft. (Pogrel MA, Podlesh S, Anthony JP, Alexander J. A comparison of vascularized and nonvascularized bone grafts for reconstruction of mandibular continuity defects. *J Oral Maxillofac Surg* 1997; 55: 1200-6. Copyright © 1997 Elsevier.)

recommends vascularized free flaps when planning reconstruction for patients with continuity defects of the mandible greater than 6-9 cm. Non-vascularized bone grafts, generally harvested from the iliac crest, are reserved for delayed reconstruction of segmental defects less than 6 cm, in whom no radiation is planned and in whom there is adequate soft tissue. The exception is in the pediatric population in whom non-vascularized bone grafts appear to be much more predictable.⁸³ Corticocancellous bone may be placed into a resorbable crib along with a reconstruction bar for added stability and precision.

Surgical treatment of malignant tumors of the jaws

Malignant tumors typically require standard neck incisions in order to obtain proper access and facilitate reconstruction. The surgery is performed on a Mayfield-type head holder which allows both optimal head positioning as well as easy intraoperative repositioning. A tracheostomy may be needed depending on the location and extent of the planned surgical resection. A neck dissection is generally required and the incision can be designed as a straight line in a prominent neck crease or as a modification of the well known Shoberger or Conley incisions. The superior and inferior skin flaps are developed in a subplatysmal plane and sutured to the adjacent skin. Classically, the cervical lymphadenectomy precedes surgical resection of the primary tumor. A combined transoral/transcervical approach is generally used for all but the largest and most posterior tumors. Lip splitting incisions are reserved for inelastic, previously irradiated skin or very large primaries. A transbuccal trocar can be used in selected cases. The primary tumor is encircled by an incision that allows a margin of at least 1 cm of grossly normal oral mucosa and at least as much normal bone around the tumor edges. The author finds that prebending a reconstruction plate prior to surgery and application of the plate prior to mandibular osteotomies (if oncologically fea-

sible) facilitates accurate reconstruction. Classically, the resection should be performed *en bloc* with the neck dissection and the tumor delivered along with the lymph node-bearing tissue. The sites of mandibular osteotomy are exposed in the subperiosteal plane on both the medial and lateral aspects, and access is obtained transorally and through the neck. Mandibulotomy is accomplished with a reciprocating saw.

Benign tumors

Odontogenic epithelium with mature, fibrous stroma without odontogenic ectomesenchyme

Ameloblastomas

The ameloblastoma is a true neoplasm of odontogenic epithelial origin. The etiology of ameloblastoma is not known with certainty but the cells of origin are thought to be ameloblasts.^{84,85} Excluding odontomas, ameloblastomas are the most common odontogenic neoplasm and account for approximately 10% of all tumors that arise in the mandible and maxilla.⁸⁶⁻⁸⁹ Some authors have suggested significant epidemiological variation based on ethnic and/or geographical differences,^{1,2,90-95} however, the literature almost certainly contains bias due to differences in tumor sampling and whether the study was performed through a dental school pathology department or a medical hospital.⁹⁶ Larsson and Almeren⁹⁷ described an incidence of 0.3 cases per million people per year in Sweden. On the other hand, studies from Africa suggest that ameloblastomas may represent more than 60% of all odontogenic tumors in that part of the world.⁹⁸

Presenting symptoms may include a slow-growing submucosal mass, loose teeth, malocclusion, paresthesia, and pain. As many as 35% of patients are completely asymptomatic and the lesions are discovered as incidental findings on routine dental radiographs. The median age at presentation is 35 years (range, 4-92 years) and there is no gender predilection.⁸⁶⁻⁹⁵ Eighty percent of ameloblastomas arise in the mandible, usually in the ramus region, and are often associated with molar teeth.

Ameloblastomas have a distinctive histological appearance manifested by columnar, basally staining cells arranged in a palisaded pattern along the basement membrane (Fig. 32.12). Six histopathologic subtypes are recognized, including follicular, acanthomatous, plexiform, basal cell, desmoplastic, and granular cell variants. Most tumors show a predominance of one pattern, but mixtures of different patterns are commonly observed. Granular cell ameloblastoma was at one time thought to be a more aggressive variant; however, this is no longer the case.⁹⁹ Reichart *et al.*⁸⁶ reviewed a large series of ameloblastomas and suggested that histological sub-

(Courtesy of Jeffery C. Stewart, DDS, MS.)

types may indeed have prognostic implications for recurrence. According to their study, the follicular type of ameloblastoma had the highest rate of recurrence at 29.5%, the plexiform subtype had 16.7% rate of recurrence, and the acanthomatous type had only a 4.5% recurrence rate. These differences were statistically significant. Too few cases of the other histological subtypes were included in the study for valid comparison, however, and there is still no consensus

as to the validity of these findings. Currently, most clinicians consider the histological subtypes to be of academic interest only and there is no convincing evidence suggesting a significant difference in biologic behavior. All ameloblastomas are benign but locally aggressive, will occasionally metastasize, and a few have malignant potential. Malignant ameloblastomas may be classified as metastasizing ameloblastoma or the more aggressive ameloblastic carcinoma.¹⁰⁰ It is thought that ameloblastic carcinoma may either arise *de novo* or as a transformation of benign ameloblastoma.¹⁰¹

As mentioned previously, the WHO has reclassified ameloblastomas into four types: (1) solid/multicystic ameloblastoma; (2) extraosseous/peripheral ameloblastoma; (3) demoplastic ameloblastoma; and (4) unicystic ameloblastoma. An entire body of literature has been devoted to explaining the various types of ameloblastomas and, unfortunately, there is still no uniform agreement on terminology. The WHO classification represents an important consensus of world leaders in the field of oral medicine, pathology, and surgery, and should be adopted in order to facilitate accurate communication and data evaluation.

Solid/multicystic ameloblastoma

Solid/multicystic ameloblastomas present as locally aggressive tumors that demonstrate inherent neoplastic cellular proliferation, are associated with high recurrence rates when inadequately treated, and represent the most clinically significant odontogenic tumor based on potential morbidity and prevalence. If left untreated, these tumors can grow to extreme sizes (Fig. 32.13). Enucleation and curettage has been associated with a recurrence rate of 60–80%.^{102–105} Neoplastic cells have been shown to be present several millimeters from the radiographic margin of the tumor,¹⁰⁶ which has led to the recommendation that resection be performed with care to maintain 1 cm tumor-free margins. This so-called radical resection generally results in local control rates greater than 90% (Table 32.6).^{102,103,105,107–110} Ghandhi *et al.*¹¹¹ recently compared the mode of presentation, treatment, and outcome of patients presenting at two different centers in different continents to investigate whether there were any significant differences in patient outcome based on geography. Fifty patients were included in the study and there were no significant differences in the clinical features on presentation (swelling, followed by pain, and altered sensation), the radiographic appearance (unilocular, 30%; multilocular, 70%), or treatment (enucleation and/or curettage, 50%; radical resection, 50%). Primary therapy by “conservative” enucleation and/or curettage led to a recurrence in approximately 80% of cases and the authors recommended “aggressive” treatment for both solid/multicystic tumors and unicystic ameloblastoma.

It is clear, based on the current body of evidence, that enucleation and curettage alone is inadequate for

Fig. 32.13 Massive ameloblastoma of the mandible. (Courtesy of Dr J.T. Arotiba.)

definitive treatment of solid ameloblastoma. Resection is the gold standard and currently offers the most predictable recurrence-free treatment for solid ameloblastoma (Fig. 32.14). For many tumors, however, resection with 1 cm tumor-free margins will commit the surgeon and patient to a segmental mandibulectomy or maxillectomy, often with sacrifice of the inferior alveolar nerve or creation of an oral–antral communication, and will necessitate primary or secondary reconstruction of continuity defects of the mandible or maxillectomy defects. Techniques have been described for segmental mandibular resection with inferior alveolar nerve preservation,¹¹² however this technique runs the theoretical risk of inviting perineural recurrence. Since ameloblastoma is a benign disease, many surgeons are reluctant to perform radical surgery on these patients. This understandable reserve has led to a number of other techniques including enucleation with peripheral ostectomy^{114,115} and/or adjuvant treatment with liquid nitrogen cryotherapy.^{53,116–118}

Cryosurgery has been used most commonly by orthopedic surgeons for the treatment of giant cell tumors of the long bones. Its use in the jaws for treatment of ameloblastoma has been limited. Curi *et al.*,¹¹⁹ treated 36 patients with ameloblastomas of the jaw with curettage and cryosurgery. They achieved a local recurrence rate of 30.6% in a follow-up of

Table 32.6 Outcomes of various treatment modalities for ameloblastomas.

Treatment method	Author	Year	Number of cases	Recurrence rate

1–10 years. Sampson and Pogrel¹¹⁸ reported no recurrence in a smaller number of patients. Early experience with these less radical approaches is promising but deserves a note of caution. The surgeon should balance the clinical findings with the patient's social situation and ability to comply with close follow-up prior to embarking on less predictable forms of therapy. Clearly a non-compliant patient, one with massive tumor growth or pathologic fracture, or a patient with no ability to return for treatment (e.g. third world country), should be managed using the technique that offers the most predictable cure with the fewest number of operations. For many patients, this will generally involve segmental resection and immediate reconstruction using free tissue transfer, or staged bony reconstruction in the form of bone grafting.

It is important to distinguish technical differences when evaluating the literature regarding recurrence rates for the treatment of ameloblastoma. The term "conservative treatment" is often used to describe a heterogeneous group of therapeutic modalities excluding segmental resection, including enucleation and curettage, excision with peripheral ostectomy, excision with margin and adjuvant treatment such as cryotherapy. Hong *et al.*¹¹³ recently performed an evaluation of 305 cases of ameloblastoma in which they considered the various clinical and histopathological factors associated with recurrence, and distinguished between "conservative treatment" (enucleation and curettage), "resection with bone margin" (no continuity defect), and "radical resection" (segmental resection or maxillectomy). The dif-

ferences between the conservative and resection with bone margin and between the conservative and segmental resection or maxillectomy was highly significant in terms of disease-free survival. The difference between the resection with bone margin and segmental resection or maxillectomy groups was not significant, however. These data suggest clearly that enucleation and curettage are associated with an unacceptably high recurrence rate; however, many patients can be spared segmental mandibulectomy or maxillectomy without sacrificing tumor control.

The author's approach for all but the most expansile tumors is generally one of transoral excision with peripheral ostectomy, with or without cryotherapy, and immediate reconstruction. In the mandible, this can usually be accomplished via a transoral and/or a transbuccal approach using various rotary instruments and/or a reciprocating saw. Endoscopic techniques and intraoperative navigation may also provide an added measure of precision when establishing adequate resection/excision margins (Fig. 32.15). If necessary, a reconstruction plate can be applied to the inferior border of the mandible to stabilize the weakened segments. Patients with larger tumors or pathologic fracture undergo segmental resection and reconstruction with a microvascular free flap (Fig. 32.16).

Maxillary ameloblastomas are rarer and often more problematic than mandibular tumors (Fig. 32.17). Although histologically identical to their mandibular counterpart, surrounding anatomy is more complex. Involvement of the maxillary sinus and nasal cavity commonly occurs and infiltration

into the orbit, pterygomaxillary space, and skull base is distinctly possible in some patients with recurrent or uncontrolled disease. Even simple enucleation and peripheral ostectomy may result in oral–antral communication and thus require reconstruction. If it is possible to perform excision with peripheral ostectomy and treatment with liquid nitrogen therapy without creating an oral–antral/oral–nasal defect, then this is the preferred treatment for most small to medium-sized lesions. Because of the reconstructive issues, however, the author's general approach for larger tumors is to perform resection and immediate reconstruction using either local or regional rotational flaps, or alternatively microvascular free flaps.

Unicystic ameloblastoma

Unicystic growth patterns are seen in approximately 6% of ameloblastomas and were first described in 1977 by Robinson and Martinez.¹²⁰ They tend to occur in a younger population (mean age 22.1 years) and a high percentage of these lesions are associated with an impacted tooth.^{121–123} They will often present as a well circumscribed, unilocular periapical radiolucency (Fig. 32.18). Histologically, the unicystic ameloblastoma shows a cystic architecture with the typical ameloblastic changes confined to the cyst-lining epithelium (Fig. 32.12b). While most pathologists accept the concept of unicystic ameloblastoma as a separate entity rather than as a precursor to solid ameloblasto-

ma, much controversy exists over the terminology and how it should be classified.

One of the contentious issues regarding unicystic ameloblastoma is related to proliferation of the ameloblastic epithelium into the lumen of the cystic cavity or into the adjacent bone.¹²⁴ Extension of the ameloblastic epithelium into the lumen of the cystic cavity is termed intraluminal, or mural proliferation. There seems to be general agreement that as long as the ameloblastic characteristics are confined to the lining epithelial layers or if it remains intraluminal, conservative therapy such as enucleation and curettage is sufficient treatment. On the other hand, transmural involvement of the epithelium and bony invasion is defined by some pathologists as solid or “invasive” ameloblastoma, a term more descriptive of its aggressive biologic behavior.¹²⁵

It is clear that some unicystic ameloblastomas have a better prognosis and less chance for recurrence than do multicystic or solid variants when treated with enucleation and curettage (10.7–60%).^{121,124,126} It is also clear that unicystic ameloblastoma is considerably more aggressive than simple dentigerous cyst,¹²⁶ with which it is included in a differential diagnosis. Ueno *et al.*¹²⁷ reported on 91 patients treated surgically between 1968 and 1985 and found that of those treated with enucleation and curettage, with or without cryotherapy, 65% of the patients with unicystic lesions were locally controlled, compared to 39% of those

Fig. 32.16 A 21-year-old with failed reconstruction following segmental resection for ameloblastoma. Patient treated elsewhere and referred for microvascular reconstruction following fracture of the reconstruction plate. (a) Preoperative panoramic radiograph. (b) Segmental resection with placement of reconstruction plate. (c) Plate fracture. (d) Reconstruction with vascularized iliac crest flap based on the deep circumflex iliac artery.

with multicystic tumors ($P < 0.05$). Furthermore, Nakamura *et al.*,¹²⁸ reporting on 78 patients treated between 1960 and 1995, found that patients with unicystic lesions tended to have a high rate of local control regardless of extent of resection, whereas those with multicystic or solid tumors had better control with segmental resection. Lau and Samman¹²⁹ recently performed a systematic review that aimed to

identify all studies pertinent to the clinical question, “Which treatment for unicystic ameloblastoma results in the lowest recurrence rate?” A structured systematic search of the literature, with predefined inclusion and exclusion criteria, using computer and manual searches as well as personal communication, was performed. The recurrence rates were 3.6% for resection, 30.5% for enucleation alone, 16% for enucleation

Fig. 32.17 Computed tomography (CT) scan of large maxillary ameloblastoma (solid).

Fig. 32.18 Panoramic radiograph of unicystic ameloblastoma.

followed by application of Carnoy's solution, and 18% for marsupialization with/without other treatment in a second phase. It was concluded that there is only weak evidence showing that jaw resection resulted in the lowest recurrence rate, followed by enucleation with application of Carnoy's solution. Enucleation alone resulted in the highest recurrence rate and treatment by marsupialization cannot be sufficiently evaluated since most cases were followed by a second stage surgery of some kind.

The clinical problem rests in the fact that the diagnosis is often made retrospectively once the patient has undergone definitive treatment for a presumptive odontogenic cyst. The issue is complicated by the fact that to definitively establish a lesion as a unicystic ameloblastoma, complete microscopic evaluation of the bony margin surrounding the lesion must be performed, therefore necessitating *en bloc* resection of the osteolytic lesion. Clearly this is impractical and would represent gross overtreatment of the vast majority of lesions. Since incisional biopsy can never provide a definitive diagnosis, it is doubtful that the

issue will be settled in the near future. The surgeon should consider all of the clinical, radiographic, and patient-related factors, provide an appropriately tailored therapy warranted by the benign nature of these lesions, and probably accept a small rate of recurrence.

Extraosseous/peripheral ameloblastoma

The peripheral or extraosseous ameloblastoma was first described in 1949¹³⁰ and was more thoroughly documented by Stanley and Krogh¹³¹ in 1959. Peripheral ameloblastoma is defined as an odontogenic tumor with the histological characteristics of its intraosseous counterpart, but occurs exclusively in the gingiva without bony involvement (Fig. 32.12c). It is thought to represent between 2% and 10% of all diagnosed ameloblastomas.¹³² Similar in appearance to basal cell carcinoma, it has been suggested that some lesions previously reported as basal cell carcinoma of the gingiva are in fact peripheral ameloblastomas.¹³³ They present as a painless, firm, exophytic growth without gender predilection and in all age groups, with a mean age of 52.¹³⁴ Seventy percent of peripheral ameloblastomas occur in the mandible, more commonly anterior to the mental foramen. Simple excision with conservative margins is all that is required for treatment and these lesions rarely recur.¹³⁵

Desmoplastic ameloblastoma

The desmoplastic variant of ameloblastoma was first described by Eversole *et al.*¹³⁶ in 1984 and probably represents between 0.9% and 12.1% of all ameloblastomas.¹³⁷ The histological pattern is characterized by extensive stromal collagenization, or desmoplasia. Immunohistochemical studies suggest that the desmoplasia originates from *de novo* synthesis of extracellular matrix proteins. The mean age at initial presentation is 41.2 years (range 18–70 years) and there appears to be equal distribution between the maxilla and mandible.¹³⁸

Desmoplastic ameloblastomas often present as an asymptomatic, slowly enlarging bony or soft tissue mass in the maxilla or mandible. Unlike other ameloblastomas, the radiographic appearance is suggestive of fibro-osseous lesions, having been described as poorly defined radiolucent/radiopaque lesions, with or without loculations.

Treatment outcomes seem to be similar to those of other ameloblastoma variants: simple enucleation results in unacceptably high rates of local recurrence and radical resection is curative.¹³⁸ Intermediate forms of therapy using a combination of peripheral ostectomy with or without cryotherapy appear to offer a practical alternative.

The role of radiation therapy on unresectable or locally advanced ameloblastoma

There are few data regarding the efficacy of radiation therapy for benign, locally advanced or unresectable

ameloblastoma. A number of authors have attempted to use external beam radiotherapy in an attempt to achieve local control with variable success. Shatkin and Hoffmeister¹³⁹ reported two patients treated with radiotherapy for benign ameloblastoma, both of which had progressive disease and one of which died of tumor-related causes. Sehdev *et al.*¹⁴⁰ reported nine patients treated with radiotherapy for gross disease between 1921 and 1951, none of whom were locally controlled: three patients had persistent disease after treatment and six patients initially responded and then progressed. More recently, however, the use of radiotherapy has been re-examined. Several authors have reported excellent local control, either as definitive treatment or as postoperative adjuvant therapy for microscopic residual disease.^{141–143} A review of these reports showed that local control was achieved in 10 of 12 patients and has led to the recommendation that radiotherapy be considered for the occasional patient with positive margins who is not amenable to resection, those with unresectable tumors, or recurrent tumors involving the skull base or vital neurological structures.¹⁴⁴

Keratinizing odontogenic tumor

Formerly known as odontogenic keratocyst (OKC), the keratinizing odontogenic tumor (KOT) is a cystic lesion of odontogenic origin that demonstrates the behavioral characteristics of a benign neoplasm and has a propensity to recur following surgical treatment. A greater understanding of the clinical behavior and molecular biology of the KOT has prompted the terminology change from OKC and led to its recent classification as an odontogenic tumor.¹⁷ The microscopic characteristics of KOTs have been well defined.^{145,146} The salient histologic features include: (1) a thin, uniform layer of epithelium with little or no evidence of rete ridges; (2) a well defined basal cell layer with palisading cuboidal or columnar cells; and (3) a corrugated, keratinizing luminal surface that is primarily parakeratinized but may be orthokeratinized or a mixture of both (Fig. 32.19). The presence of “satellite” or “daughter” cysts has been recognized in a significant minority of KOTs and inflammation is an inconsistent finding. The radiographic appearance of KOTs is that of a unilocular or multilocular radiolucency, often with cortical expansion or erosion (Fig. 32.20).

Recurrence rates following initial treatment range as high as 62% and have prompted as yet unanswered questions about the pathophysiology of recurrence associated with this unique lesion.¹⁴⁷ Various theories have been popularized that correlate the potential for recurrence with the presence of “daughter” or “satellite” cysts remaining in the epithelium following enucleation, the presence of a thin cystic lining, incomplete removal of the cyst, or remnants of dental lamina not associated with the original cyst.^{148–151} Recent advances within the fields of

Fig. 32.19 Histological appearance of keratinizing odontogenic tumor (H&E). (Courtesy of Jeffery C. Stewart, DDS, MS.)

Fig. 32.20 Panoramic radiograph of keratinizing odontogenic tumor. Note multilocular appearance, cortical expansion, and erosion.

molecular genetics and immunocytochemistry may revolutionize our understanding of KOTs and, in time, render these time-honored explanations rudimentary in nature.^{152–154}

There is a growing body of evidence that a distinction should be made between parakeratinized KOTs, which have a relatively high risk of recurrence, and the orthokeratinized variant, which rarely recurs.^{145,146,155,156} Crowley and colleagues¹⁵⁷ reviewed 449 cases of KOT and separated them into parakeratinized, orthokeratinized, and mixed groups. The large majority of cysts were parakeratinized (86.2%) and there was no difference between the three groups with respect to age, race, sex, presenting symptoms, or clinical impression. Significantly, 42.6% of the parakeratinized group developed a recurrence, compared to only 2.2% of the orthokeratinized group. The subsequent identification of a histochemical marker (38-kD cell surface glycoprotein-gp38) found in basal cell carcinomas that was expressed within the basal and suprabasal epithelial cell membranes of parakeratinized KOTs, but not orthokeratinized KOTs, has led some authors to conclude that a distinction should be made between the two variants.^{158–160}

The aggressive nature of KOTs has been documented in numerous case reports and is manifested by cortical erosion,¹⁶¹ soft tissue involvement,¹⁶² and extension into the skull base,^{163–164} orbit,¹⁶⁵ and infratemporal fossa.¹⁶⁶ Studies published over the last three decades have reported recurrence rates following initial treatment with a variety of procedures that ranged from 2.5% to 62.5%.^{41–47,167–181} Myriad surgical strategies have been proposed to facilitate complete removal of the lesion and to minimize recurrent or residual disease, including more meticulous surgery with or without peripheral ostectomy, tissue fixation methods, soft tissue excision, radical treatment when necessary, and more conscientious follow-up. The optimum treatment modality has yet to be realized.

As previously stated, recurrence rates as high as 62.5% have been reported for KOTs that were treated with simple enucleation and curettage. Zhao *et al.*¹⁸² recently reported on the long-term outcome of 255 patients with KOTs treated by enucleation and curettage ($n = 163$), enucleation plus Carnoy's solution ($n = 29$), marsupialization plus enucleation ($n = 11$), and resection ($n = 52$). With follow-up of 3–29 years, the overall recurrence rate was 12.16%. Statistical comparison of the demographics of each group showed no difference with regard to site, age, or sex. However, there was a significant difference between groups with respect to method of treatment: KOTs treated by simple enucleation and curettage demonstrated a 17.79% recurrence rate compared to those treated with Carnoy's solution (6.70%, $P < 0.05$), marsupialization and resection (0.0%, $P < 0.01$). Some authors have proposed conservative management of recurrent KOTs based on close follow-up and repeated curettage, performed as recurrences develop.⁴² Given this documented propensity to recur after treatment, however, it seems that management of KOTs with simple enucleation should be avoided.

Stoelting⁴⁷ published the results of a prospective clinical trial conducted on 82 OKCs diagnosed in 80 patients over a 25-year period. Thirty-three patients underwent simple enucleation and curettage while 38 patients underwent excision of the overlying mucosa attached to the cyst where it had perforated through the bone, followed by treatment of the lesion with Carnoy's solution, enucleation of the cyst, and curettage of the bony cavity (Fig. 32.21). Five patients in the Carnoy's group presented with a recurrent tumor. With follow-up that ranged from 2 to 25 years there was an overall recurrence rate of 11% (nine patients). Most of the recurrences (six) occurred in the patients who were treated with enucleation and curettage alone. None of the patients presenting with recurrent lesions rerecurred following treatment using the authors' protocol. Of those with recurrence, six patients presented without signs or symptoms and the cyst was noticed on routine radiograph. There did not appear to be a correlation between age, sex, or site and recurrence.

Schmidt and Pogrel⁵⁴ recently published the results of 26 patients with KOTs who were treated with enucleation and cryotherapy. The majority of these cystic lesions ($n = 22$) were recurrent lesions. With follow-up of 2–10 years, recurrence was noted in three patients (11.5%). Complications were limited to wound dehiscence and local infection. The authors concluded that enucleation and liquid nitrogen cryotherapy may offer patients improved therapy in the management of KOTs.

There is little published data documenting the long-term outcome of patients with KOTs treated with marsupialization.^{183,184} Brondum and Jensen¹⁸⁵ found no recurrences among 12 patients with OKCs that were treated with decompression of the cyst cavity followed by cystectomy. Zhao *et al.*¹⁸² found no recurrences among 11 patients treated with marsupialization plus enucleation, with follow-up of at least 3 years. Recently, Pogrel and Jordan¹⁸⁶ and Pogrel¹⁸⁷ have published on the concept of carrying out marsupialization and decompression as definitive treatment for KOTs. These studies reported complete resolution and cure of these lesions based on clinical, histological, and radiographic evidence. Since that time, however, the investigators have published a partial retraction.¹⁸⁸ It has become apparent with long follow-up that recurrences may occur in as much as 12% of the cases.¹⁸⁷ Recurrences were detected at different time intervals, from 1.5 years to longer than 4 years. While no firm conclusions can be made from these small case series, this technique may be useful for the primary management of very large mandibular lesions in an effort to minimize surgical morbidity and/or the size of the reconstruction defect. Its role in the treatment of KOT remains ill defined but might be considered in two situations. Those lesions that have greatly expanded the shape of the mandible or have replaced the maxillary sinus would benefit from initial shrinkage and such shrinkage may very well allow a much more thorough secondary procedure (Fig. 32.22). In the case of mandibular lesions, initial marsupialization may help avoid pathologic fracture. The second area of utility of marsupialization for either primary or recurrent lesions is in the elderly or otherwise poor surgical candidate. Proper marsupialization may provide excellent palliative care in this patient group.

Resection is the only predictably curative procedure for patients with KOTs that offers a recurrence rate approaching zero.¹⁸² The concern with this method, of course, is the functional and esthetic morbidity associated with continuity defects of the mandible and maxilla. Advances in head and neck reconstruction, microvascular surgery, and dental implants during the last two decades, however, have made this aggressive treatment modality less foreboding (Fig. 32.23). The need for resection might be answered by this question: is the reconstructive utility of the residual osseous structure less than what could be provided entirely from distant tissue? If so, the resection and composite reconstruction would be appropriate.

Fig. 32.21 A 34-year-old female with KOT involving the left mandible treated with enucleation and curettage with chemical fixation using Carnoy's solution. (a) Preoperative panoramic radiograph. (b) Preoperative CT scan. (c) Intraoperative photograph following enucleation and curettage (note inferior alveolar nerve). (d) Treatment with 5 minute application of Carnoy's solution. (e) Conservative peripheral ostectomy with rotary instrument. (f) Freeze-dried, demineralized bone graft reconstruction.

Based on the current level of evidence, treatment of most KOTs should involve enucleation and curettage with some sort of adjunctive procedure if resection is not a consideration (Table 32.7). The use of Carnoy's solution as a chemical fixative or cryotherapy as a thermal fixative appears to be a safe, effective way to predictably eradicate lesions with minimal morbidity. Alternatively, for larger tumors, decompression and marsupialization followed by cystectomy appears to offer a reasonably effective treatment.

Squamous odontogenic tumor

The squamous odontogenic tumor (SOT) was first described by Pullon *et al.*¹⁸⁹ in 1975. It is rare, with fewer than 50 cases having been reported.¹⁹⁰ Other synonymous terms were previously used to describe this tumor, including benign epithelial odontogenic tumor, acanthomatous ameloblastoma, acanthomatous ameloblastic fibroma, hyperplasia and squamous metaplasia of residual odontogenic epithelium, and benign odontogenic tumor unclassified.¹⁹¹ SOT is defined as a locally infiltrative neoplasm consisting of islands of well differentiated squamous epithelium

Fig. 32.22 Extensive KOT of the mandible treated with marsupialization prior to conservative excision. (a) Preoperative panoramic radiograph. (b) Marsupialization (note drains in place). (c) Panoramic radiograph after marsupialization for 1 year and conservative, outpatient excision. (Courtesy of Bryce E. Potter, DMD, MD, FACS.)

Fig. 32.23 Recurrent KOT of the left mandibular ramus with extension to the infratemporal fossa. The patient had been treated with three previous operations during a 20-year period, two of them aggressively through a transcutaneous approach. The full extent of the recurrent lesion involves not only the mandible but also the infratemporal fossa, parotid gland, and temporalis muscle, extending to the skull base. (a) Panoramic radiograph of the patient demonstrating multilocular radiolucency, however the extensive involvement cannot be appreciated on plain film, demonstrating the need for additional imaging. (b) Axial CT scan of the same patient demonstrating extensive involvement by KOT of the mandible, infratemporal fossa, parotid gland, and skull base. Note also the proximity of the lesion to skin. (c) CT of the same patient demonstrating cranial extension of the lesion with involvement of the temporalis muscle and skull base. (d) Panoramic radiograph demonstrates long-term result of the same patient 7 years after undergoing composite resection of the mandible and infratemporal fossa and superficial parotidectomy, with immediate reconstruction utilizing a fibular free flap. Note evidence of osseous healing, restoration of mandibular continuity, and no evidence of recurrent disease. (e) Clinical photograph of the patient 7 years after surgery. Note well healed parotidectomy scar and excellent restoration of form and function. (Courtesy of Eric J. Dierks, DMD, MD, FACS.)

Table 32.7 Treatment outcome for keratinizing odontogenic tumors.

Authors	Year	Number of patients	Treatment method	Rate of recurrence
Pindborg and Hansen ¹⁴⁷	1963	16	Enucleation or marsupialization	62.5%
Browne ¹⁴⁸	1971	85	Marsupialization or enucleation	24.7%
Brannon ¹⁴⁹	1976	312	Enucleation	12%
Vedtofte and Praetorius ¹⁷²	1979	72	Enucleation or marsupialization	51%
Voorsmit <i>et al.</i> ¹⁷³	1981	40	Enucleation, excision of mucosa; Carnoy's solution	2.5%
Brondum and Jensen ¹⁸⁵	1991	12	Decompression followed by cystectomy	0%
Schmidt and Pogrel ⁵⁴	2001	22	Enucleation and cryotherapy	11.5%
Zhao <i>et al.</i> ¹⁸²	2002	163	Enucleation and curettage	17.8%
Zhao <i>et al.</i> ¹⁸²	2002	29	Enucleation and Carnoy's solution	6.7%
Zhao <i>et al.</i> ¹⁸²	2002	11	Marsupialization and enucleation	0%
Zhao <i>et al.</i> ¹⁸²	2002	52	Resection	0%
Pogrel ¹⁸⁸	2007	42	Marsupialization	12%

in a fibrous stroma.^{192,193} The age range is broad (8–74 years, mean = 38.7) and there is no gender predilection. The etiology is unknown. The tumor typically presents as a localized gingival swelling or extraosseous mass in the maxilla or mandible with possible tooth mobility, pain, and gingival erythema.

Histologically, SOTs are composed of rounded or oval islands of well differentiated squamous epithelium within a fibrous stroma (Fig. 32.24). Individual islands may contain calcified material and may undergo central microcystic degeneration. Rests of Malassez may be the source of the epithelial proliferation for lesions that are associated with the alveolar process adjacent to the root surface,^{189,190} whereas the dental lamina has been implicated in the development of tumors associated with the crowns of unerupted or impacted teeth.^{194,195}

SOTs do not generally behave aggressively, however they can present as multiple lesions,¹⁹⁶ erode into cortical bone,¹⁹¹ and cause cortical expansion.¹⁹⁴ One case of malignant variant has been reported.¹⁹⁷ Treatment is by conservative surgical excision and recurrences are rare.

Calcifying epithelial odontogenic tumor

The calcifying epithelial odontogenic tumor (CEOT) is defined as a locally invasive epithelial odontogenic neoplasm, characterized by the presence of amyloid material that may become calcified.¹⁹⁸ First described by Pindborg in 1955,¹⁹⁹ the tumor is often referred to as a Pindborg tumor. Fewer than 200 cases have been reported in the literature and it is thought to represent approximately 1% of all odontogenic tumors.²⁰⁰ The tumor has been reported to occur in patients between 13 and 80 years of age and has no gender predilection.²⁰¹ The majority of cases occur in the mandible (3:1 ratio) and the premolar area is a common site.

The CEOT usually presents as an asymptomatic, slow-growing, expansile mass in the mandible or maxilla. More than 90% of the cases are intraosseous, but extraosseous variants have been reported. Radiographically, they have been described as a well defined, unilocular or multilocular, mixed radiolucent/radiopaque lesion, however these findings are variable.²⁰²

Histologically, the tumor is characterized by islands and sheets of polyhedral epithelial cells with abundant eosinophilic cytoplasm, sharply defined cell borders and well developed intercellular bridges, within a fibrous stroma (Fig. 32.25).¹⁹⁸ The nuclei are often pleomorphic and mitotic figures are rarely encountered. Homogeneous, eosinophilic hyalin material is present and confirmed by positive staining with Congo red and fluorescence with thioflavine T. Liesegang rings are calcifications in concentric

(Courtesy of Jeffery C. Stewart, DDS, MS.)

shapes that can occur within the amyloid and account for the radiopacities. Clear cells make up a significant proportion of the tumor, which is thought to arise from the stratum intermedium tissue of the developing enamel organ. Generally there is no nuclear pleomorphism, however there are reports of CEOT demonstrating malignant features.^{203,204}

CEOT is a locally invasive tumor that is associated with recurrence rates of 14–20% following enucleation and curettage.^{201,205,206} Slightly higher rates of recurrence have been associated with the clear cell variant. The occurrence of malignant transformation to odontogenic carcinoma ex Pindborg tumor is extremely rare, but has been reported.²⁰⁷ Although thought to be less aggressive than the solid ameloblastoma, excision with 0.5–1.0 cm margins is generally recommended. The same controversies that surround radical resection of ameloblastomas are applicable to CEOT and the clinician is cautioned to weigh all pertinent clinical, pathological, and social variables prior to recommending definitive surgical therapy.

Adenomatoid odontogenic tumor

The adenomatoid odontogenic tumor (AOT) is a unique lesion involving the jaws (centrally located), or in the soft tissue (gingival) overlying tooth-bearing areas or alveolar mucosa in edentulous regions. It is defined by the WHO as a tumor of odontogenic epithelium in a “variety of histoarchitectural patterns, embedded in a mature connective tissue stroma and characterized by slow but progressive growth”.²⁰⁸ Typically the tumor is made up of a cellular multinodular proliferation of spindle, cuboidal, and columnar cells in a variety of patterns; usually scattered duct-like structures, eosinophilic material, and calcifications in several forms; and a fibrous capsule of variable thickness (Fig. 32.26). It is regarded by

some authors as a benign neoplasm and by others as a developmental hamartoma. The first reported case was probably that of Harbitz in 1915,²⁰⁹ termed an “adamantoma”. Prior to and since that time, the literature has provided a confusing array of terms and descriptions.²¹⁰ In 1909 James and Forbes²¹¹ described the tumor as an “epithelial odontome”. Several years later, Wohl²¹² referred to it as a “tooth germ cyst of the jaw”. Stafne²¹³ reported the first series of AOT in 1948 under the title “epithelial tumors associated with developmental cysts of the maxilla”. Additional terms that have been used in the past to describe this tumor but have now been discarded include: adenoamantoblastoma,²¹⁴ adeno-ameloblastoma,²¹⁵ cystic complex composite odontome,²¹⁶ unusual pleomorphic adenoma-like tumor in the wall of a dentigerous cyst,²¹⁷ tumor of enamel organ epithelium,²¹⁸ adenomatoid ameloblastoma,²¹⁹ adenomatoid odontoma,²²⁰ ameloblastic adenomatoid tumor,²²¹ and odontogenic adenomatoid tumor.²²² Finally, Philipsen and Birn²²³ proposed the name adenomatoid odontogenic tumor in 1969, a term that was adopted by the WHO in 1971.¹¹

AOTs account for approximately 2–7% of all odontogenic tumors.^{223,224} They occur in almost any age group (3–82 years), however more than 90% are diagnosed prior to age 30 and half of the cases occur in adolescence. The male:female ratio is approximately 1:1.9 and AOT may be more prevalent in Asians.²²⁵ The most common site is in the anterior maxilla, with a 2:1 (maxilla:mandible) ratio.

AOTs are often detected on routine radiographic evaluation as an asymptomatic intraosseous lesion associated with an unerupted permanent tooth, commonly a maxillary canine. When intraosseous growth causes cortical expansion, it may present as a slow-growing, painless, bony mass, but peripheral variants are also described. The characteristic radiographic appearance is that of a well defined, unicystic radio-

lucency associated with the crown of an impacted tooth. The radiolucency shows focal areas of radiopacity in two thirds of the cases of intraosseous tumor.

Three histologically identical variants have been described: intraosseous follicular (70%); extrafollicular (26%); and peripheral (4%).²²⁶ Variably sized solid nodules of cuboidal or columnar cells of odontogenic epithelium that form nests or rosette-like structures with minimal stromal connective tissue are noted microscopically. Eosinophilic amorphous material ("tumor droplets") is present between the epithelial cells and in the center of the rosette-like configurations.

The biological behavior of this tumor is more hamartomatous than neoplastic, although aggressive variants are occasionally encountered. Treatment is with conservative local excision and recurrences are unusual.

Odontogenic epithelium with odontogenic ectomesenchyme with or without hard tissue formation

Ameloblastic fibroma/fibrodentinitoma

Along with odontoameloblastoma and dentinogenic ghost cell tumor, the ameloblastic fibroma (AF) is one of the benign "mixed" odontogenic tumors that is a true neoplasm characterized by expansile growth and potentially destructive behavior. It lies in contradistinction to the other "mixed" odontogenic tumors, ameloblastic fibro-odontoma and odontoma, which represent hamartomas that rarely result in significant morbidity. The AF consists of "odontogenic ectomesenchyme resembling the dental papilla and epithelial strands and nests resembling dental lamina and enamel organ", which distinguishes them from tumors of purely ectomesenchymal or pure epithelial origin.²²⁷ Generally, no dental hard tissues are present; however, if dentin is observed, the lesion is referred to as an ameloblastic fibrodentinitoma.²²⁸ It has been suggested that some cases in childhood may represent the primitive stage of a developing odontoma, however there are distinct differences between these entities.²³² AF tends to occur in the first two decades of life, but patients older than 22 years are not uncommon. The posterior mandible is affected in more than 70% of the cases.^{1,229} The tumor presents as a unilocular or multilocular radiolucency that may demonstrate cortical expansion, erosion or both.²³⁰ Chen *et al.*²³² recently published an extensive review of the English language literature since the first description of AF in 1891. A total number of 123 cases with well documented follow-up data were identified and an overall recurrence rate of 33.3% was reported in cases that were treated by conservative (91.5%) and/or radical (8.5%) means. Despite these findings, most authors recommend conservative excision, particularly in young patients, and find that the lesions

rarely recur.^{227,233} The author's approach is that of excision with peripheral ostectomy and adjuvant cryotherapy (Fig. 32.27). The patients are followed closely and if a recurrence occurs it is typically small and readily managed on an outpatient basis. Malignant transformation has been widely reported, however, so these patients must be followed for a significant period of time following definitive surgical extirpation.²³⁴

Ameloblastic fibro-odontoma

One of the "mixed" odontogenic tumors, the ameloblastic fibro-odontoma most likely represents a hamartoma, rather than a true neoplasm. It has been suggested that the ameloblastic fibro-odontoma is simply an immature complex odontoma. Histologically, it shares the same features of ameloblastic fibroma, except that it contains dentin and enamel.²³⁵ The tumor typically presents as an asymptomatic, well circumscribed, mixed radiopaque/radiolucent mass involving the posterior mandible.²³⁵ Rarely exhibiting aggressive behavior, the tumor is treated effectively with enucleation and curettage.²²⁹⁻²³⁵ Recurrence after conservative treatment is rare. Malignant transformation has been reported.

Odontoma, complex and compound type

Odontomas are the most common of the odontogenic tumors, represent a benign hamartoma rather than a true neoplasm, and generally have a benign clinical course. Odontomas are described in two types: complex and compound. The difference between the two forms is that compound odontomas contain recognizable enamel, dentin, and sometimes cementum, shaped in toothlike structures; whereas complex odontomas are composed of irregular masses of dentin and enamel and have no anatomic resemblance to a tooth.²³⁶ Complex odontomas are typically found in the posterior maxilla or mandible and compound odontomas are predominately in the anterior maxilla. The compound odontoma is twice as common as the complex odontoma.²³⁷ The lesions appear as well circumscribed, radiopaque masses, often surrounded by what appears to be a periodontal ligament (Fig. 32.28). The masses are treated with simple enucleation and curettage, which is virtually always curative.

Odontoameloblastoma

According to the WHO, odontoameloblastoma (OA) "combines the clinical and histological features of ameloblastoma with those of an odontoma".²³⁸ This is a rare neoplasm (fewer than 50 cases have been reported) that occurs in the maxilla and mandible with equal prevalence, usually in the first 3 decades of life.²³⁹ Clinical signs and symptoms, as well as biological behavior, may be identical to those of a solid

Fig. 32.27 Ameloblastic fibroma of the mandible treated by excision with peripheral ostectomy and cryotherapy. (a) Preoperative panoramic radiograph. (b) 1 year postoperative panoramic radiograph. (c) Small recurrence noted on cone-beam CT scan 2 years following treatment. (d) Postoperative panoramic radiograph 2 years following conservative, outpatient excision of recurrence. (Courtesy of Eric J. Dierks, DMD, MD, FACS.)

ameloblastoma.²⁴⁰ The radiographic appearance of this tumor differs from that of ameloblastoma by varying amounts of radiopaque material, which generally represents displaced or unerupted teeth. The histological appearance consists of islands and cords of odontogenic epithelium demonstrating follicular and plexiform patterns, in addition to a variable amount of cellular myxoid tissue that contains mineralized dental tissues in the form of odontomas.²³⁸ Similar to conventional ameloblastoma in its biological behavior, OA is locally aggressive and requires

surgical excision with 0.5–1.0 cm tumor-free margins.^{239–243} The same treatment-related controversies that surround optimal treatment of ameloblastoma are presumably shared by this rare neoplasm.

Calcifying cystic odontogenic tumor

Calcifying cystic odontogenic tumor (CCOT) is a benign odontogenic neoplasm that resembles ameloblastoma with ghost cells that may calcify.²⁴⁴ First described by Gorlin *et al.*²⁴⁵ in 1962, it is also termed

Fig. 32.28 Complex odontoma of the mandible.

Gorlin cyst and calcifying odontogenic cyst. The CCOT may present as an expansile mass involving the maxilla or mandible with equal frequency, and both intraosseous and extraosseous forms occur.²⁴⁶ It can occur at any age and there is no gender predilection.^{247,248} It typically presents as an asymptomatic, unilocular, well defined radiolucency, however it can exhibit a radiopaque component as well. Histologically, the CCOT is characterized by a cyst wall that is lined by thin ameloblastomatous epithelium with the formation of ghost cells (Fig. 32.YY).²⁴⁴ Ledesma-Montes *et al.*²⁴⁹ recently attempted to clarify and group the clinicopathological features of a number of CCOT cases from around the world and proposed a clinically useful classification under the 2005 WHO guidelines. CCOT was divided into four subtypes: (1) simple cystic; (2) odontoma associated; (3) ameloblastomatous proliferating; and (4) CCOT associated with benign odontogenic tumors other than odontomas. Aggressive clinical behavior is not typical of this benign entity, and simple enucleation and curettage is generally curative.^{247,248,250}

Dentinogenic ghost cell tumor

Formerly considered a solid variant of the calcifying odontogenic cyst (Gorlin cyst), the dentinogenic ghost cell tumor is a locally invasive neoplasm characterized by ameloblastoma-like islands of epithelial cells in a mature connective tissue stroma, with varying amounts of dysplastic dentin and ghost cells.²⁵¹ The tumor typically presents as an asymptomatic hard tissue or soft tissue mass (intraosseous or extraosseous variants), showing varying amounts of bone resorption or tooth displacement. Radiographically, it may present as a radiolucent or mixed radiolucent/radiopaque lesion with unilocular, well circumscribed borders. It is histologically distinguished from ameloblastoma and calcifying odontogenic tumor by the presence of ghost cells with dysplastic dentin. Although malignant transformation has been described, recurrences after appropriate excision with 0.5–1.0 cm margins are rare.²⁵² Similar challenges to

ameloblastoma are present with regards to the most appropriate surgical treatment and the extent of resection.

Mesenchyme and/or odontogenic ectomesenchyme with or without odontogenic epithelium

Odontogenic fibroma

The odontogenic fibroma (OF) is a very rare neoplasm that is defined by the WHO as containing “varying amounts of inactive-looking odontogenic epithelium embedded in a mature fibrous stroma”.²⁵³ Two histological subtypes have been described: epithelial poor (formerly termed simple type) and epithelial rich (formerly termed complex or WHO type). The OF occurs as a radiolucent lesion involving the jaws without respect to gender, age, or site (maxilla or mandible).²⁵⁴ The radiographic appearance is that of a radiolucent lesion that may be unilocular or multilocular and cause cortical expansion.²⁵⁵ Although aggressive variants have been described, neither subtype appears to behave in an aggressive fashion and both respond well to enucleation and curettage.^{256,257} Brannon recently reviewed 73 well documented cases of odontogenic fibroma (epithelial rich) as reported in the English literature. Most patients underwent some variant of enucleation and curettage. Follow-up information greater than 1 year was available in 27 cases, for which a recurrence rate of 26% was reported.²⁵⁴

Odontogenic myxoma/myxofibroma

The odontogenic myxoma (OM) is relatively common amongst odontogenic tumors and may comprise between 3 and 20% of all such lesions.²⁵⁷ It is the second or third most common odontogenic tumor with a reported incidence of 0.07 new cases/million people/year.²⁵⁴ The WHO characterizes this intraosseous neoplasm as containing “stellate and spindle-shaped cells embedded in an abundant myxoid or mucoid

extracellular matrix" (Fig. 32.29).²⁵⁸ The term myxofibroma is used when a relatively greater amount of collagen is evident.

Two thirds of OMs are located in the mandible, commonly in the molar regions, and typically present in the second to fourth decade of life (age range 1–70 years) without gender predilection.²⁵⁹ It is commonly found as an incidental finding on routine panoramic radiograph. The radiographic appearance is that of a well defined, unilocular or multilocular radiolucency, generally associated with an erupted tooth. The tumor typically appears as a hyperintense signal in contrast-enhanced magnetic resonance imaging (MRI); these lesions are identified due to their high proton density associated with water bound to the myxoid stroma.

The lesion has a rather bland histological appearance that is characterized by a loose mesenchymal fibrous tissue that lacks atypia.²⁵⁸ Randomly oriented stellate, spindle-shaped and round cells with eosinophilic cytoplasmic processes sit in a mucoid or myxoid stroma. OM has a similar histological appearance to that of hyperplastic dental follicles and the dental papilla of a developing tooth. Clinical correlation is essential to avoid misdiagnosis.

The OM is a benign but locally aggressive tumor that is probably less aggressive than ameloblastoma, but can result in progressive growth with skull base involvement if left untreated. Malignant variants have been described.²⁶⁰ Barker's review of the literature suggested an overall recurrence rate of between 10% and 33%.²⁶¹ Several authors have advocated conservative therapy and have claimed success;^{262–264} however, others have found poor results with enucleation alone.^{265–267} Resection with 1–1.5 cm bony margins and one uninvolved anatomic barrier margin has been advocated as the best chance for a curative treatment due to its potentially aggressive behavior.^{268,269} The author's approach to smaller lesions is typically enucleation with peripheral ostectomy. Larger lesions that exhibit aggressive biological behavior, such as cortical erosion or recurrence following treatment, should be excised with 0.5–1.0 cm tumor-free margins, and/or consideration should be

given to adjunctive treatment in the form of Carnoy's solution or cryotherapy.

Cementoblastoma

Cementoblastoma is a rare lesion that comprises less than 1% of all odontogenic tumors.²⁷⁰ It is characterized by the formation of a radiopaque cementum-like mass intimately associated with the root of a tooth (usually a lower second or third molar). The tooth typically remains vital and symptoms include varying degrees of cortical expansion and pain. Classically, the tumorous mass is surrounded by a radiolucent ring that represents the periodontal ligament (Fig. 32.30). Histologically identical to an osteoblastoma, the cementoblastoma is differentiated from its bony counterpart by virtue of its intimate association with teeth.²⁷¹ Biopsy will distinguish it from an odontoma, focal sclerosing osteomyelitis, and hypercementosis, all of which may have a similar clinical and radiographic appearance. Gigantiform variants have been encountered, requiring radical resection and reconstruction with free tissue transfer.²⁷² Treatment is otherwise by excision with peripheral ostectomy for all but the largest tumors. Recurrence is possible if incompletely excised.

Fig. 32.29 Odontogenic myxoma. Coronal CT scan demonstrating well defined expansile mass with displacement of teeth.

Non-odontogenic benign tumors

Ossifying fibroma

Ossifying fibroma (OF) is one of the so-called fibro-osseous lesions that include ossifying fibroma, fibrous dysplasia, and cemento-osseous dysplasia. Formerly known as cemento-ossifying fibroma, and thought to be derived from the periodontal ligament, this benign neoplasm is characterized by the replacement of normal bone by fibrous tissue and varying amounts of newly formed bone or cementum-like material. The WHO recognizes two distinct histological variants, neither of which differ from each other significantly in their biological behavior or treatment: juvenile trabecular ossifying fibroma (JTOF) and juvenile psammomatoid ossifying fibroma (JPOF).²⁷³ The juvenile variants occur in a younger age group than the conventional type of ossifying fibroma. The mean age for JPOF is 20 years, compared to that of 35 years in cases of adult ossifying fibroma, whereas the mean age range for JTOF is 8.5–12 years.²⁷⁴

OF is primarily found in the posterior mandible, JPOF occurs in the bony walls of the paranasal sinuses, and JTOF commonly presents in the maxilla.²⁷⁵ All variants of OF generally present as painless, slow-growing, expansile osseous lesions. The radiographic appearance is typically a well defined expansile mass with a variable degree of internal calcification (Fig. 32.31). Root displacement and root resorption may be seen.

Histologically, OF is composed of fibrous tissue with variable cellularity and a mineralized compo-

nent that consists of woven bone, lamellar bone, and possibly cementum-like material. The most important distinguishing histological feature of OF from that of fibrous dysplasia is the presence of demarcation and/or encapsulation of OF, as opposed to the ill defined borders seen in fibrous dysplasia.²⁷³ JTOF consists of cell-rich fibrous tissue containing bands of cellular osteoid without osteoblastic rimming with immature bone lined by enlarged osteoblasts.²⁷³ JPOF, on the other hand, is characterized by a fibroblastic stroma containing small ossicles resembling psammoma bodies.²⁷³

A number of chromosomal abnormalities have been associated with OF.^{275–277} All three histological subtypes harbor neoplastic growth potential, and may exhibit aggressive, destructive behavior if left untreated. Most adult forms of OF, however, do not display the same infiltrative pattern seen in ameloblastoma, and seem to be less aggressive than their juvenile counterparts.²⁷⁸ Conventional therapy includes appropriate excision dependent on the extent and location of the tumor, with recurrence rates reported between 1 and 63%.^{278–283} Some authors advocate more extensive surgery for lesions that exhibit aggressive behavior,^{284,285} however this approach should be tempered based on various clinical and social factors. Large paranasal tumors, for example should be excised so as to prevent skull base and intracranial extension. Minimally invasive, endoscopic techniques are now available to treat many of the aggressive skull base tumors, obviating the need for more conventional craniofacial resection.

Fig. 32.31 Coronal CT scan of an ossifying fibroma of the maxilla with extension into the paranasal sinuses and anterior skull base.

Fibrous dysplasia

Fibrous dysplasia (FD) is a genetically based sporadic, non-odontogenic disease of bone that is characterized by the replacement of bone with benign fibrous tissue and that may affect single (monostotic) or multiple (polyostotic) bones throughout the human skeleton. Fibrous dysplasia involving only multiple adjacent craniofacial bones (termed craniofacial fibrous dysplasia) is regarded as monostotic.

The monostotic form has no gender or racial predilection, but is six times more common than the polyostotic form.²⁸⁶ Polyostotic FD has a female to male ratio of 3:1. The majority of cases are due to a sporadic mutation in the GNAS I gene, which encodes for the alpha-subunit of a signal transducing G-protein (Gs-alpha).^{287,288} Modulation of G protein results in increased cyclic AMP production which affects proliferation and differentiation of preosteoblasts and the phenotypic expression of FD.

FD presents most commonly in the long bones, followed by the jaws (maxilla more than mandible), base of skull, and ribs.²⁸⁹ Patients with craniofacial FD typically complain of painless swelling, facial asymmetry, loosening of teeth, malocclusion, and root resorption. Lesions encroaching on the orbital apex may cause visual impairment. Temporal bone

involvement has the potential to result in hearing loss. Uncontrolled growth in the maxilla or sphenoid can produce profound cranial neuropathies. Children that exhibit café-au-lait spots should be evaluated to rule out McCune–Albright syndrome.

The radiographic appearance has classically been described as that of a “ground glass” appearance with ill defined borders and cortical expansion (Fig. 32.32).²⁹⁰ In fact, there is a spectrum of appearances that includes an early-phase radiolucent appearance, a midphase appearance characterized by sclerosis, and a later phase that demonstrates a mixed

radiolucent/radiopaque character. Computed tomography (CT) is the imaging modality of choice, and three-dimensional reconstructions and stereolithographic models are useful in determining the extent of involvement and in planning surgery.

The histological appearance of FD is that of cellular fibrous tissue with spindle-shaped cells and immature, trabeculated woven bone (Fig. 32.33).²⁸⁶ Bundles of collagen fibers can be identified that are characteristically oriented perpendicular to the bony surface. Osteoblastic rimming can be noted, which may represent long-standing, mature lesions.

Fig. 32.32 Craniofacial fibrous dysplasia exhibiting active growth and progressive deformity in a 25-year-old male. (a) CT scan demonstrating homogeneous, expansile bony lesion with “ground glass” appearance. (b) Coronal approach combined with transoral and periorbital incisions to facilitate complete resection of the involved bone. (c) Resection specimen. (d) Stereolithographic model ground down to normal anatomic contours and resected according to the planned surgery. (e) Full-thickness calvarial bone harvested, milled to reproduce the ground down model, and inset into the stereolithographic model to achieve proper fit and symmetry. (f) Stereolithographic model demonstrating proper arch projection and symmetry. (*cont’d*)

Fig. 32.33 Histological appearance of fibrous dysplasia. (Courtesy of Richard Slavin, MD.)

FD can often exhibit aggressive, destructive behavior prior to skeletal maturity; however, it often becomes indolent in adulthood. Encroachment on vital anatomic structures, such as the orbital apex or cranial foramina, mandates careful observation and/or surgical intervention if neurological deterioration is deemed eminent. Surgical recontouring or complete excision/resection can also be contemplated in cases of persistent deforming growth or in those patients that request it due to esthetic or functional concerns. Recent technological advances in computer-assisted surgery, presurgical planning using stereolithographic models, and intraoperative navigation have

armed the surgeon with a useful adjunct with which to restore these patients to form and function, with improved accuracy and predictability (Fig. 32.32).

Osseous dysplasias

Osseous dysplasias (ODs) are defined by the WHO as “idiopathic processes located in the periapical region of the tooth-bearing jaw areas, characterized by a replacement of normal bone by fibrous tissue and metaplastic bone”.²⁹¹ The terminology for this lesion is confusing due to the numerous synonyms that are used based on the site of occurrence within the jaws: in the anterior mandible the lesion has been referred to as periapical osseous dysplasia; and in the posterior mandible it is known as focal osseous dysplasia (formerly focal cemento-osseous dysplasia); periapical cemental dysplasia is a term used to describe this lesion in association with the roots of teeth; and florid osseous dysplasia describes widespread involvement of the mandible in multiple quadrants. The latter form may present with symptoms of pain or secondary infection, but the vast majority of these lesions are asymptomatic and are of no clinical significance. A rare variant that exhibits extensive and persistent expansion that can result in severe facial deformity has been reported and is referred to as a gigantiform cementoma.

The histological appearances of the various expressions of this lesion are identical: cellular fibrous tissue

surrounding sheets and strands of woven and lamellar bone interspersed between masses of cementum-like material. OD resembles ossifying fibroma and fibrous dysplasia and clinical correlation is often required to make an accurate diagnosis.²⁹²

OD does not require treatment unless complications occur (usually resulting from ill advised surgical exploration). When asymptomatic, the lesions should be observed for their clinical behavior. Biopsy should be performed in cases that demonstrate progression, cortical expansion or bony erosion. Aggressive surgical treatment is rarely needed except in the extremely unusual case of gigantiform cementoma.

Central giant cell lesion

The central giant cell lesion (CGCL) is a benign but potentially aggressive proliferation of fibroblasts and multinucleated giant cells that cause osteolysis and reactive bone formation. The CGCL was previously termed a central giant cell granuloma and central giant cell reparative granuloma in reference to the inaccurate belief that this tumor represented a reactive process. The proliferating cell in this lesion appears to be the fibroblast, which produces cytokines resulting in the recruitment of monocytes, which subsequently transform into multinucleated giant cells.^{293,294} Controversy exists with regards to whether the CGCL is unique to the jaws or whether it represents a continuum of the same disease process that affects the long bones (termed giant cell tumor).

CGCL of the jaws is most often diagnosed in children and young adults under the age of 30 years. One third of the patients are diagnosed under 20 years of age.²⁹⁵ The mandible is more often involved than the maxilla and the posterior mandible is affected more often than the anterior aspect of the jaws or the ascending ramus. The histological appearance is very similar to that of the giant cell tumor found in long bones, however some distinction has been made between the two entities by virtue of nuclei size, distribution of the giant cells, stromal cellularity, and necrosis.²⁹⁶

The lesion typically consists of spindle-shaped fibroblastic cells loosely arranged in a fibrous connective tissue stroma with areas of hemorrhage, hemosiderin deposits, macrophages, lymphocytes, granulocytes, and plasma cells (Fig. 32.34).²⁹⁷ Small clusters of osteoclast-like giant cell are found dispersed within the lesion. Mitoses are frequently observed. Brown tumor of hyperparathyroidism is histologically indistinguishable from CGCL, therefore a serum parathyroid hormone level is generally recommended to rule out primary or secondary forms of parathyroid dysfunction.

Clinical manifestations of the disease may include painless cortical expansion, facial asymmetry, cortical perforation, and/or root resorption (Fig. 32.35). Giant cell lesions have been classified as non-aggressive,

Fig. 32.34 Histological appearance of giant cell lesion. (Courtesy of Richard Slavin, MD.)

intermediate, or aggressive, based on clinical and radiographic criteria.^{298–301}

Complete excision of the tumor is required to prevent the sequela of persistent bony growth. Enucleation and curettage has been the primary mode of treatment, but is associated with an overall recurrence rate of between 15 and 50%.³⁰⁵ Non-aggressive lesions can be treated successfully by simple curettage, with a very low recurrence rate. Aggressive lesions, on the other hand, have recurrence rates as high as 70% after enucleation and curettage.^{298–305} There are no currently biological markers available to predict clinical behavior, and there is no association between histological appearance and biological behavior. Because of this high rate of recurrence and unpredictable behavior, a number of authors have described various therapeutic modalities to be used as an adjunct to conservative excision of these benign lesions.

The first non-surgical modality to be successfully applied was intralesional corticosteroid injections.³⁰⁶ Weekly injections of triamcinolone for 6 weeks have resulted in partial or complete resolution in some patients.^{306–309} Experience with this technique is varied, however, and response to therapy is unpredictable. Calcitonin has also been proposed as a definitive, non-surgical treatment for giant cell lesions, presumably based on its inhibition of osteoclastogenesis.^{310–313} Pogrel *et al.*³¹⁴ have popularized the use of subcutaneous calcitonin injections and demonstrated some success with daily subcutaneous injections carried out for approximately 18 months. To date, they have completed treatment of 27 patients with subcutaneous calcitonin and have had two failures.³¹⁴ de Lange *et al.*³¹⁵ published the only prospective, placebo-controlled randomized trial studying the efficacy of intranasally administered calcitonin. The researchers compared tumor reduction in 14 patients and found no differences between those patients treated with placebo and those treated with calcitonin. Complete remission was not observed in any patient. Finally, Kaban and colleagues³¹⁶ proposed the use of alpha-interferon given by subcutaneous injection as an

Fig. 32.35 Giant cell lesion of the mandible in a 17-year-old female. (a) Preoperative appearance with mild facial asymmetry. (b) Preoperative cone beam CT scan demonstrating multilocular, expansile lesion with cortical erosion. (c) Axial CT scan demonstrating cortical expansion and mandibular deformity. (d) Transoral excision with peripheral osteotomy and immediate anterior iliac crest bone graft reconstruction. (e) Specimen. (f) Postoperative panoramic image of the patient 2 years following surgery with maintenance of mandibular continuity and no evidence of tumor recurrence. (g) Postoperative appearance 2 years after surgery.

adjunct to surgical excision. The data thus far suggest that alpha-interferon treatment may result in less radical surgery and a reduced rate of recurrence, however this is not yet conclusive.^{298,317} Furthermore, treatment with alpha-interferon is associated with significant side-effects and potential morbidity and mortality. A recent report was published detailing the outcome of 26 patients treated at the Massachusetts

General Hospital according to a protocol of enucleation with preservation of nerves and teeth followed by treatment with interferon alpha-2a (Roferon A, Roche Laboratories, Nutley, NJ) at a dose of 3 million units/m² administered once per day by subcutaneous injection.³¹⁷ At the time of publication, all patients were either cured or in remission. Four patients enrolled in the study were unable to complete inter-

feron treatment due to significant side-effects (15%) and one of these patients required *en bloc* resection for control of residual/recurrent disease.

Brown tumor of hyperparathyroidism

Altered calcium regulation resulting from primary or secondary hyperparathyroidism or renal dysfunction can result in the formation of giant cell lesions of bone termed brown tumors due to the hemosiderin deposition within the lesion that causes a brown color (Fig. 32.36). Hyperparathyroidism is characterized by the overproduction of parathyroid hormone (PTH). Primary hyperparathyroidism is the uncontrolled production of PTH as the result of a parathyroid adenoma or adenocarcinoma. Secondary hyperparathyroidism occurs in response to hypocalcemia and is most often associated with chronic renal failure. These lesions are clinically and histologically identical to those of central giant cell lesions.

Patients with giant cell lesions should be evaluated for the presence of altered PTH levels, hypercalcemia (seen in primary hyperparathyroidism), hypocalcemia (secondary hyperparathyroidism), or impaired renal function. Brown tumors will typically resolve with treatment of the underlying metabolic abnormality.

Fig. 32.36 Brown tumor of hyperparathyroidism.

Persistent, locally destructive lesions that are recalcitrant to medical therapy should be surgically excised.^{318,319}

Cherubism

Cherubism is a rare hereditary condition that is characterized by giant cell lesions which cause symmetrical expansion of the jaws. First described in 1933, it follows an autosomal dominant pattern of inheritance with 100% penetrance in males, 50–75% penetrance in females, and variable expressivity.³²⁰ The genetic defect has been mapped to chromosome 4p16.3, which encodes the binding protein SH3BP2.^{321–324}

Cherubism is generally diagnosed in early childhood (14 months to 4 years). Mandibular involvement is most prominent, although both jaws may be affected and the process may extend into the anterior and inferior orbits. The mandibular condyles are spared. With involvement of the maxillary contribution to the orbital floor, the globes may be displaced upward, resulting in scleral show and the “looking toward Heaven” appearance that inspired the lesion’s name.

The radiographic appearance is that of bilateral multilocular radiolucencies exhibiting cortical expansion, premature exfoliation of teeth, and a “soap bubble” appearance (Fig. 32.37). The histological appearance is indistinguishable from the central giant cell lesion, but may be distinguished by the presence of hemosiderin deposits, stromal fibrosis, and perivascular cuff-like collagen deposits.

The clinical course is generally indolent. The lesions regress as the patient approaches skeletal maturity. Treatment is not recommended unless severe dysfunction is present.³²⁵

Aneurysmal bone cyst

The aneurysmal bone cyst (ABC) is defined by the WHO as an osteolytic lesion “with blood filled spaces separated by fibrous septa containing osteoclast-type giant cells and reactive bone”.³²⁶ ABCs often present

Fig. 32.37 Cherubism. Panoramic radiograph demonstrating bilateral multilocular radiolucencies exhibiting cortical expansion, premature exfoliation of teeth and “soap bubble” appearance.

as a secondary event within another bone lesion, a finding that has led some authors to question the existence of this lesion as a separate entity. Furthermore, as it often occurs within a central giant cell lesion and itself contains giant cells, other authors have suggested that the ABC is simply part of the spectrum of development in giant cell lesions. While many of these lesions are thought to be reactive, there are some cytogenetic data that suggest ABCs are indeed a distinct entity.

ABC is rare, with an incidence estimated to be 0.014 per 100 000.³²⁷ It occurs in young patients, generally below age 30 and with a peak incidence in the second decade. ABC may occur in virtually any bone in the body, and involvement of the jaws occurs in less than 3% of the cases.³²⁸ When present in the maxilla or mandible, it may present as an asymptomatic radiolucency discovered incidentally on routine dental radiography, or may present with marked facial swelling, similar to fibrous dysplasia (Fig. 32.38). Teeth remain vital and the same functional problems associated as regards encroachment on vital structures or foramina that exist in fibrous dysplasia are concerns with ABC.

The histological appearance of ABC is that of hemorrhagic, multilocular, well circumscribed blood-filled cavities that are lined by macrophages, not endothelial cells.³²⁹ Fibroblasts, osteoclast-like giant cells, and reactive bone are dispersed within osteoid, occasionally containing hemosiderin deposits and nuclear mitoses.

Genetic evidence supporting the classification of ABC as a distinct pathological entity is derived primarily from research in extracranial lesions: a 17p-rearrangement with balanced translocation with 16q has been reported by a number of investigators.^{330–333} These translocations have been regarded by some authors as resulting from acquired aberrations that provide evidence that some ABCs are clonal proliferations.

ABCs are typically treated with enucleation and curettage.³³⁴ The lesions can be highly vascular, therefore removal in an office setting is generally ill

Fig. 32.38 Aneurysmal bone cyst. Axial CT scan of ABC demonstrating expansion and cortical erosion through the anterior and medial wall of the maxillary sinus.

advised for all but very small lesions. Appropriate hemostatic measures should be readied prior to surgery and even embolization has been applied successfully.^{335–337}

Simple bone cyst

The simple bone cyst (SBC) is an intraosseous pseudocyst that is devoid of an epithelial lining and may be empty or filled with serosanguinous fluid. Formerly known as a traumatic bone cyst or idiopathic bone cavity, the etiology is unknown. The most common age for presentation is in the second decade with no gender predilection.³³⁸ The mandible is the most often affected facial bone, generally, but not always, presenting in the anterior aspect.³³⁸

Most SBCs are discovered as an incidental finding of a unilocular radiolucency found on routine dental radiography. Most patients are asymptomatic, although rarely cortical expansion or teeth displacement has been reported. The histological appearance is that of a connective tissue lining covering bone with a membrane-like layer.³³⁹

Diagnosis and treatment generally occur at the same time and consist of enucleation and curettage.³⁴⁰ Occasionally, larger lesions or difficult to access sites require a more complex approach for definitive therapy.

Odontogenic carcinomas

Malignant odontogenic tumors are classified by the WHO as odontogenic carcinomas and odontogenic sarcomas.³⁴¹ All of these tumors are exceedingly rare and many are still reportable cases. They are classified as odontogenic if the tumor demonstrates epithelium that histologically resembles that seen in a developing tooth or recognizable odontogenic tumor, such as ameloblastoma or ameloblastic fibroma.

Ameloblastic carcinoma

Malignant ameloblastoma is subclassified into four distinct entities (Table 32.8),³⁴² three of them only of academic importance: (1) metastasizing ameloblastoma; (2) ameloblastic carcinoma – primary type; (3) ameloblastic carcinoma – secondary type (dedifferentiated), intraosseous; and (4) ameloblastic carcinoma – secondary type (dedifferentiated), peripheral. Metastasizing ameloblastoma is differentiated from ameloblastic carcinoma by its benign histologic appearance, despite its ability to metastasize. Ameloblastoma with metastatic deposits that exhibit cellular atypia is defined as ameloblastic carcinoma. Secondary ameloblastic carcinoma, either intraosseous or peripheral, arises in a pre-existing benign ameloblastoma.

All variants of ameloblastic carcinoma are histologically characterized by tall columnar cellular mor-

phology and pleomorphism, mitotic activity, focal necrosis, perineural invasion and nuclear hyperchromatism may be present (Fig. 32.39).³⁴² Peripheral palisading and inverted nuclear polarity will be present along with a stellate reticulum.³⁴² Aneuploidy has been found to be more frequently present in the ameloblastic carcinoma and may be used as a strong predictor of malignant potential of questionable lesions.³⁴³ Recently 5q13 amplification was demonstrated by comparative genomic hybridization.³⁴⁴

The incidence of ameloblastic carcinoma is unknown, as fewer than 70 cases have been reported. Benlyazid *et al.*³⁴⁵ recently reviewed the existing literature and found 66 well documented cases. The median age of these patients was 44 years, however the tumor occurred in a wide age range of patients, with a sex ratio of 1.75 male to 1 female. The mandible was involved more frequently than the maxilla (ratio 2.14:1). Ameloblastic carcinoma seems to behave similarly to squamous cell carcinoma in terms of local invasion, regional lymph node metastasis, and distant metastasis. Of the 66 patients reviewed, 20 died of disease, and 15 developed distant metastasis.

Fig. 32.39 Ameloblastic carcinoma. Histologic appearance characterized by tall columnar cellular morphology with pleomorphism, mitotic activity, focal necrosis, perineural invasion, and nuclear hyperchromatism. (Courtesy of Yi-Shing Lisa Cheng, DDS, MS, PhD.)

Excluding those patients with inadequate follow-up, the 5-year disease-specific survival rate was 67.8%.

Optimal treatment of ameloblastic carcinoma is unknown, but there is general agreement that it should be managed in similar fashion to squamous cell carcinoma of the oral cavity, consisting of composite resection with 1 cm tumor-free margins, neck dissection, and immediate reconstruction with microvascular free flaps.^{345,346} Adjuvant radiation therapy should be considered for all patients, especially those cases exhibiting unfavorable histologic characteristics, such as positive resection margins, perineural invasion, and lymph node metastasis.

Primary intraosseous squamous cell carcinoma

Primary intraosseous squamous cell carcinoma (PIOSCC) is a central jaw carcinoma derived from epithelium arising within benign odontogenic cysts or tumors, usually a dentigerous cyst or keratinizing odontogenic tumor (formerly odontogenic keratocyst).³⁴⁷ The incidence of malignant transformation of odontogenic cysts has been estimated to be approximately 0.12%, with keratinizing cysts demonstrating a higher incidence than non-keratinizing cysts.³⁴⁸ While originally thought to be extraordinarily rare, intraosseous squamous cell carcinoma of the jaws is becoming more frequently recognized. Gardner³⁴⁹ reviewed the literature from 1889 to 1967 and found only 25 examples of carcinoma arising from an odontogenic cyst. Yasuoka and colleagues³⁵⁰ identified an additional 50 cases from 1967 to 2000. The author's review of the literature revealed fewer than 60 cases of carcinoma arising in odontogenic cysts reported since 1967, and 13 of them were keratinizing odontogenic tumors.^{348–364} The average age of patients presenting with carcinoma arising within a cystic lining is 58.8 years with a range of 25–84 years.³⁵⁰ The most common sites are generally the same as for non-malignant cysts, most commonly the mandibular third molar, maxillary canine and third molar, and mandibular second premolar regions.

Diagnosis of so-called carcinoma ex-odontogenic cyst is challenging. It is often difficult to determine if the cancer arose from a cystic epithelium, oral mucosal epithelium, salivary gland tissue or *de novo*. Criteria for a diagnosis of carcinoma arising in a cyst have been defined by Gardner and are as follows: (1) a microscopic transition area from benign cystic epithelial lining to invasive malignant squamous cell carcinoma; (2) no carcinomatous change in the overlying epithelium; and (3) no source of carcinoma in the adjacent structures.^{349,365} Occasionally, the diagnosis of squamous cell carcinoma is made in the presence of a cystic lesion thought to be a recurrent keratocyst.

A high degree of suspicion must be maintained by the clinician if the cyst demonstrates abnormally aggressive behavior, ulceration, or neurosensory

changes, or if the patient develops cervical lymphadenopathy. Any suspicion should warrant a biopsy prior to definitive management. The role of tumor markers such as p53 is being defined. As the technology progresses, immunohistochemistry and other molecular genetic studies will aid in the diagnosis and potentially provide prognostic information on which to base treatment.

Treatment is similar to that of invasive squamous cell carcinoma with bony involvement: radical resection with ipsilateral neck dissection and immediate reconstruction using microvascular composite free flaps. Although data are lacking, adjuvant radiation therapy or chemoradiation therapy should be considered depending on the tumor's histopathological characteristics, margin status, and the status of the regional lymph nodes.

Clear cell odontogenic carcinoma

Clear cell odontogenic carcinoma (CCOC) is defined by the WHO as a malignant odontogenic tumor that is characterized by sheets and islands of vacuolated and clear cells. Previously known as clear cell ameloblastoma or clear cell odontogenic tumor, fewer than 40 cases have been reported since the early 1990s.^{367–369} There is a strong female predilection and it tends to occur in the mandible of older patients, with a mean age at diagnosis of 60 years.

The histological appearance is that of a fibrous stroma with islands of epithelial cells revealing clear to faintly eosinophilic cytoplasm, well demarcated cell membranes, and irregular dark-staining nuclei. The clear cells are positive for cytokeratin and negative for vimentin and mucicarmine, S-100 protein, desmin, smooth muscle actin, HMB 45, and alpha antichymotrypsin, which differentiates it from other clear cell tumors such as mucoepidermoid carcinoma, renal carcinoma, and CEOT.³⁶⁹ Regional and distant metastasis have been described and should be treated in similar fashion to squamous cell carcinoma. Adjuvant radiation therapy should be considered following composite resection, neck dissection, and microvascular free flap reconstruction.

Ghost cell odontogenic carcinoma

Ghost cell odontogenic carcinoma is a malignant odontogenic epithelial tumor that is defined by the WHO as having “features of calcifying cystic odontogenic tumor and/or dentinogenic ghost cell tumor”.³⁷⁰ This tumor is extremely rare, having been reported less than two dozen times in the English literature. It may be more common in Asia, appears to affect more men than women, and occurs in a wide age range. Twice as many tumors occur in the maxilla as in the mandible, similar to that of the calcifying odontogenic cyst.

Histological diagnosis is based on the identification of malignant epithelial cells within the histologi-

cal architecture of a calcifying cystic odontogenic tumor. Ghost cells are found in varying numbers. Immunohistochemical overexpression of p53 protein has been reported.³⁷¹ PCNA labeling may also be used to assist in diagnosis.

The clinical presentation is typical of the malignant osseous lesions. Imaging may demonstrate an osteolytic radiolucency with or without calcifications, which is poorly defined, may displace or destroy tooth roots, and extend into adjacent tissues. Treatment data are lacking; however, presumably the lesion should be managed with radical resection, neck dissection, and immediate reconstruction using composite free tissue transfer.^{370–374} Adjuvant radiation therapy or chemoradiation therapy should be considered, depending on the histopathologic features, margin status, and status of the cervical lymph nodes.

Odontogenic sarcomas

Odontogenic sarcomas are very rare tumors. The WHO defines two distinct types: ameloblastic fibrosarcoma and ameloblastic fibrodentinosa and fibro-odontosarcoma.³⁷⁵

Ameloblastic fibrosarcoma

The ameloblastic fibrosarcoma (AFS) is the malignant counterpart of the ameloblastic fibroma. An odontogenic tumor with a benign epithelial and a malignant ectomesenchymal component, the etiology is unknown. Many of these tumors appear to represent malignant transformation of pre-existing ameloblastic fibroma.³⁷⁵ They can occur at virtually any age (3–89 years), however most cases are diagnosed in the second decade of life.³⁷⁵ Patients with pre-existing ameloblastic fibroma appear to develop malignant tumors later than those patients whose tumor arises *de novo*.³⁷⁹ Two thirds of the patients are males and the mandible is the most common site of occurrence.

The clinical presentation of AFS is that of an expansile intraosseous lytic mass with ill defined borders, cortical erosion, and pain.³⁷⁹ The histological characteristics are those of ameloblastic fibroma in which the epithelium is benign, but the connective tissue component is malignant. The connective tissue stroma displays mitotically active cells surrounding the bland epithelial component.

The biological behavior of AFS appears to be somewhat less aggressive than the hard and soft tissue counterparts, such as osteosarcoma or rhabdomyosarcoma.^{375–380} Of more than 60 reported cases, only one had metastasis (mediastinal and liver).

Ameloblastic fibrodentinosa and fibro-odontosarcoma

The WHO defines these rare tumors as containing the histological features of ameloblastic fibrosarcoma,

together with dysplastic dentin (fibrodentinosarcoma) and/or enamel/enameloid and dentin/dentinoid (fibro-odontosarcoma).³⁷⁵ This tumor is extremely rare (14 cases in the literature). The histological appearance is typical of ameloblastic fibrosarcoma, except that the dental hard tissues are also dysplastic. The biological behavior seems to be less aggressive than that of other sarcomas and is generally regarded as low grade.^{379,380} Only one case has demonstrated an ability to metastasize. Treatment is radical resection and the prognosis appears to be good.

Non-odontogenic malignant jaw tumors

Osteosarcoma

Osteosarcoma (OS) is a malignant tumor of bone characterized by the formation of osteoid by neoplastic cells. OS is the most common primary sarcoma of bone and only plasma cell neoplasms outnumber this tumor in the category of all primary bone tumors. It has been classified as central type, which is more common and arises from the medullary portion of the bone, and peripheral or juxtacortical type, which is less common and originates on the surface of bone. OS may develop from pre-existing bone disorders such as Paget's disease, giant cell tumors, or fibrous dysplasia, or from prior radiation therapy, but most arise *de novo*. The molecular mechanisms associated with the pathogenesis of OS are related to a variety of genetic alterations involving tumor suppressor genes, oncogenes, and complex chromosomal abnormalities.³⁸¹

Central osteosarcomas most often involve the distal femur and proximal tibia of patients in their second decade of life. OS involving the jaws accounts for 5–7% of all OS, but the presentation appears to be older, more often presenting in the third or fourth decade of life. There is a slight male predilection and the mandible is more commonly affected than the maxilla.

The clinical presentation of OS is commonly that of jaw pain and swelling. Paresthesia is common in mandibular lesions, as is loosening of teeth. Nasal obstruction, epistaxis, proptosis, or diplopia may all be presenting signs or symptoms in advanced maxillary lesions. The radiographic appearance of central OS is classically that of an osteolytic lesion that is associated with symmetrical widening of the periodontal ligament and extracortical bone producing a "sunburst" appearance. In fact, the radiographic appearance is quite variable and can range from that of a dense radiopacity to a mixed radiopaque and radiolucent lesion to a radiolucent lesion (Fig. 32.40). The "sunburst" quality is a non-specific finding, as are cortical destruction and root resorption which are also commonly found.

The histological appearance of OS of the jaws is similar to that of other primary mesenchymal malignant neoplasms and characterized by pleomorphic spindle cells producing a variable amount of osteoid. The lesions are classified as osteoblastic, chondroblastic, and fibroblastic, depending on the relative amounts of osteoid, cartilage, or collagen that is produced by the malignant stroma. The osteoblastic type is the most common in the axial skeleton, but the chondroblastic type is most common in the jaws. A telangiectatic subtype of OS has been described which contains large blood-filled spaces and prominent multinucleated giant cells.³⁸² A small cell variant, similar to Ewing sarcoma has also been described in the jaws.³⁸³ The histologic subtypes do not predict prognosis. Indeed, biological behavior is best predicted by histologic grade, with high-grade lesions portending a poor prognosis.

Treatment for all subtypes includes radical resection (Fig. 32.40). The most important prognostic indicator of successful outcome is negative resection margins. Consequently, bone margins of up to 3 cm have been recommended. Well-designed, prospective outcome data for OS of the jaws are lacking. Radiation therapy, either as definitive treatment or in the adjuvant setting has not been shown to be beneficial.^{384,385} Current treatment strategies that employ a multimodal approach incorporating preoperative and postoperative chemotherapy for cases involving the long bones have resulted in dramatic survival improvement when compared to previous outcomes.³⁸⁵ Current recommendations for craniofacial OS include preoperative and postoperative chemo-

Fig. 32.40 (cont'd) (i) Fibular flap harvested. (j) Inset of the flap.

therapy in addition to radical resection and free flap reconstruction.³⁸⁶⁻³⁹⁹

In contrast to the central medullary OS, the peripheral OS may be less aggressive and is associated with a more favorable prognosis in long bones. There are two subtypes of peripheral OS: parosteal and periosteal. The parosteal variant appears as a radiodense mass on the cortical surface or the maxilla or mandible. Peripheral OS arises from a broad pedicle and enlarges along the cortical surface in a pedunculated fashion. A radiolucent line is noted between the tumor and the underlying cortex. Daughter masses may be seen in the region as well. The periosteal type lacks the pedunculated growth pattern and is usually not as radiodense. It is also thought to have a higher recurrence rate and greater metastatic potential in comparison with the parosteal subtype.

Most reports cite an overall 5-year survival rate for head and neck OS of 40–70%. Metastasis occurs in approximately 18–50% of cases, generally occurring in the lungs. The hematogenous route does not invite regional lymph node involvement and therefore cervical lymphadenectomy is not advocated.

Chondrosarcoma

A chondrosarcoma (CS) is a malignant tumor characterized by the formation of cartilage by malignant tumor cells. Only 1% or 2% of all chondrosarcomas are located in the head and neck. It is the second most common primary sarcoma of bone. Unlike osteosarcoma, chondrosarcoma is more frequent in the maxilla than the mandible. The maxillary lesions occur most often in the anterior region and the mandibular tumors occur most often in the posterior mandible. CS occurs over a wide age range without gender predilection, and generally occurs in the third decade of life.⁴⁰⁰

The most common clinical presentation is that of a slow-growing, painless mass in the involved anatomic region. The radiographic appearance is variable, although most lesions demonstrate an osteolytic process with ill defined margins, cortical erosion, and destructive behavior. Radiopacities are often present.

Similar to osteosarcoma, there may be a “sunburst” pattern with symmetrical widening of the periodontal ligament space around involved teeth.

The histological appearance of CS is characterized by variable amounts of cartilage formation, but not osteoid or bone, emanating from a sarcomatous stroma. If the malignant cellular elements are noted to produce osteoid or bone in any portion of the tumor, it is considered an osteosarcoma. Calcification of the chondroid matrix does occur in CS, however. The hypercellular tumor exhibits an increased number of cartilage cells with plump nuclei, binuclear or multinuclear cartilage cells, nuclear hyperchromatism, and cellular and nuclear pleomorphism. Mitotic figures may be scarce or absent. CS has been classified into grades I, II, and III on the basis of mitotic rate, cellularity, and nuclear size, all of which correlate with prognosis.⁴⁰²

The treatment of choice for CS is radical resection. Unlike osteosarcoma, chemotherapy has not been shown to be of significant therapeutic benefit.^{400,402} Radiation therapy may be considered in cases of unresectable, residual, or recurrent tumors. The prognosis for CS of the jaws is worse than that for tumors of the axial skeleton. The overall 5-year survival for CS of the jaws ranges from 32–81%.⁴⁰⁰⁻⁴⁰⁴ Factors influencing the prognosis include the site of origin, histological grade, treatment modality, and adequacy of the surgical resection. Mandibular tumors have a more favorable prognosis than maxillary tumors. Increasing grade correlates with worsening prognosis.⁴⁰⁵⁻⁴⁰⁷ Like osteosarcoma, the lung is the most common site of metastasis and cervical lymph nodes are generally not involved. Neck dissection is therefore not recommended.

Ewing sarcoma

Ewing sarcoma (ES) is one of the “small, round, blue cell” tumors and is in the family of tumors that includes the primitive neuroectodermal tumors. These tumors are characterized by a recurrent t(11;22)(q24;q12) chromosomal translocation, which is detectable in approximately 85% of cases (Fig. 32.41). ES accounts

Fig. 32.41 Diagnosis of Ewing sarcoma: histology, immuno-histochemistry, and molecular analysis. (a) H&E stain. (b) Vimentin. (c) Neuron specific enolase (NSE). (d) CD99. (e) Map of dual color EWSR1. (Courtesy of Anne Rader, MD.)

for 6–8% of primary bone malignancies, although it is second to osteosarcoma as the most common sarcoma in bone and soft tissue in children. The pelvis and lower extremities are most commonly affected. Jaw tumors account for less than 3% of ES. ES primarily presents in children and young adults, usually under 20 years of age. A male predilection exists.

The clinical signs and symptoms usually include rapidly progressing pain and swelling (Fig. 32.42). Tumor expansion may also cause paresthesia or tooth mobility. The radiographic appearance is that of other malignant jaw tumors, including an osteolytic process with ill defined borders and displacement or resorption of teeth or tooth roots. Growth may be rapid and progressive. Metastatic disease is present in 15% of the patients with non-pelvic tumors at the time of diagnosis.

The histological appearance is that of closely packed cells that may be compartmentalized by fibrous bands, with round to oval nuclei, and finely dispersed chromatin. The cytoplasm of the tumor cell frequently stains with periodic acid-Schiff stain.

Patients should be evaluated by specialists from all disciplines (e.g. radiologist, medical oncologist, pathologist, surgeon, and radiation oncologist) as early as possible. Appropriate imaging studies of the site should be obtained prior to biopsy. The surgeon who will perform the definitive surgery should be involved prior to or during the biopsy so that the incision can be placed in an acceptable location. The radiation oncologist and pathologist should be consulted prior to biopsy/surgery in order to be sure that the incision will not compromise the radiation port and so that multiple types of tissue samples are obtained; including fresh tissue for cytogenetics and flow cytometry, frozen tissue, and formalin-fixed tissue.

The successful treatment of patients with Ewing family of tumors (EFT) requires systemic chemotherapy^{408–414} in conjunction with either surgery or radiation therapy or both modalities for local tumor control.^{415–419} In general, patients receive preoperative chemotherapy prior to instituting local control measures. In patients who undergo surgery, surgical margins and histologic response are considered in

(j) Postoperative photograph 3 months following surgery demonstrating resolving lymphedema, complete facial nerve function, and favorable esthetics.

planning postoperative therapy. In the Euro-Ewing study, patients who receive radiation alone for local control are stratified by pretreatment tumor volume for postradiation therapy.⁴²⁰ Most patients with metastatic disease have a good initial response to preoperative chemotherapy; however, in most cases, the disease is only partially controlled or recurs.^{420–423} Patients with lung as the sole metastatic site have a better prognosis than patients with metastases to bone and/or bone marrow.

Randomized clinical trials during the last 15 years have led to general acceptance of the combination of vincristine, doxorubicin, and cyclophosphamide as standard therapy for Ewing sarcoma.^{420–424} With these drugs and adequate treatment of the primary tumor, about 60% of patients with localized disease

can be cured. For patients with metastatic disease at diagnosis, the prognosis is much worse, with only 30–40% surviving long-term. Phase III clinical trials are underway using alternating cycles of vincristine–doxorubicin–cyclophosphamide and ifosfamide–etoposide, with granulocyte colony stimulating factor (filgrastim, G-CSF) for intensification of chemotherapy. Interdisciplinary cooperation is essential, particularly for complex head and neck tumors.^{425,426}

Malignant peripheral nerve sheath tumor

Malignant peripheral nerve sheath tumors (MPNSTs) comprise a rare group of tumors that arise from peripheral nerves or that display differentiation along

Fig. 32.43 A 21-year-old male with malignant peripheral nerve sheath tumor involving the anterior and lateral skull base. (a) Pretreatment axial MRI demonstrating massive tumor with extensive involvement of the anterior and lateral skull base. (b) Outline of the planned composite resection of the anterior and lateral skull base via a transcranial and infratemporal fossa approach to include resection of the maxilla, mandible, temporal bone with facial nerve sacrifice and interpositional nerve graft, orbital exenteration, and partial pharyngectomy with immediate reconstruction using a rectus muscle free flap. (c) Intraoperative photograph demonstrating the infratemporal fossa approach to the lateral skull base with disarticulation of the zygoma and neck dissection for vascular access. (d) Intraoperative photograph demonstrating lateral temporal bone resection with exposure of the sigmoid sinus, division of the facial nerve, and mobilization of the flap forward exposing the temporal bone. (*cont'd*)

the lines of the various elements of the nerve sheath, including Schwann cells, perineural fibroblasts, or fibroblasts. This group of tumors was previously referred to as malignant schwannoma, neurofibrosarcoma, or neurogenic sarcoma. MPNSTs account for about 5% of all soft tissue sarcomas. Although approximately half of the patients with this disorder will have a history of neurofibromatosis type 1, many cases will arise *de novo*, or as a postradiation sarcoma. Generally occurring in the extremities or trunk, they are seldom found in the head and neck area. The most common site in the head and neck for intraosseous tumors is the mandible, although skull base tumors originating various cranial nerves are relatively frequent. Patients generally present with a rapidly growing mass, pain, and/or neurosensory distur-

bance within the anatomic distribution of the involved region or nerve.

Radiographically, tumors of the mandible may produce widening of the inferior alveolar canal or the mental foramen. More commonly, they invade the mandible from adjacent structures or cranial nerves (Fig. 32.43). The microscopic appearance is that of fascicles of spindle cells that closely resemble the cells of fibrosarcoma. The nuclei may be wavy or comma shaped and nuclear pleomorphism may be present. MPNSTs are S-100 protein positive in 50% of cases.

MPNST is considered one of the most aggressive malignant lesions in the head and neck, with 5-year overall survival reported to be between 5–58%, depending on tumor size, location status of surgical

Fig. 32.43 (cont'd) (e) Intraoperative photograph of the ablative defect following craniectomy and resection of the tumor. (f) Replacement of the uninvolved temporal bone and fat graft to the mastoid defect. (g) Harvest of the rectus muscle free flap. (h) Wound closure.

margins, stage, grade, association with neurofibromatosis type 1 (NF1), and a history of previous radiation therapy.^{427–436} Complete surgical removal with negative resection margins is the most important prognostic indicator.^{427,430,434,435} Data are lacking regarding the role of adjuvant or neoadjuvant chemotherapy or radiation therapy, and these tumors have traditionally been thought to be relatively resistant to radiation and chemotherapy. Adjuvant radiation therapy has been used to assist in local control, despite the margin status at the time of surgery.^{430,434,437,438} The use of adjuvant chemotherapy in the form of ifosfamide/doxorubicin has been advocated for pediatric MPNSTs and its use in adults should be considered for patients with residual disease after initial surgery and in grade 3 tumors larger than 5 cm.^{430,434} Unresectable disease can be treated with chemotherapy in an attempt to shrink the tumor to resectable proportions, although data from this approach are lacking and prognosis remains dismal.⁴³⁴ Based on the current body of evidence, treatment recommendations are as follows: (1) complete surgical removal with as wide a margin of normal tissue as is feasible to achieve negative margins; (2) adjuvant radiation therapy and chemotherapy based on residual disease

after initial surgery, tumor size, and grade; (3) immediate reconstruction with free tissue transfer as appropriate.

Metastatic carcinoma

Metastatic carcinoma is the most common form of malignancy affecting bone. While the jaws are relatively uncommon sites for distant metastasis, bones with active marrow spaces such as vertebrae, ribs, pelvis, and skull are generally considered preferential sites for dissemination. Metastatic carcinoma has previously been thought to represent approximately 1% of all malignant jaw lesions. More recent data based on autopsied carcinoma cases, however, demonstrate that 16% of the mandibles have microscopic deposits of metastatic tumor cells, despite the lack of radiographic evidence of osteolysis. Metastatic spread of carcinoma to the jaws occurs by a hematogenous route, most commonly from the breast or lung, but also from the kidney, prostate, thyroid, colon, and rectum. Emboli of primary carcinomas may enter the venous circulation and bypass the lungs via the valveless prevertebral venous plexus of Batson to deposit in the jaws.

Fig. 32.44 Panoramic radiograph demonstrating bronchogenic carcinoma metastatic to the left mandibular condyle.

Metastasis to the jaws is much more common in the mandible than in the maxilla. Radiographically, a metastatic lesion appears as a poorly circumscribed radiolucency with cortical erosion, expansion and destruction of local anatomy, including tooth roots (Fig. 32.44). In the presence of known malignancy, the diagnosis is often made clinically or with confirmatory biopsy. If the primary lesion is occult (not yet identified) the histopathology and immunohistochemistry may be correlated with whole body CT and positive emission tomography (PET) to identify the site of origin.

Treatment is usually palliative and aimed at controlling symptoms and local extension into vital structures. This is commonly in the form of focused radiotherapy or systemic therapy based on the histopathologic diagnosis. Occasionally, surgery may be indicated to provide local control for radio-resistant tumors or in patients that have developed pathological fracture. The prognosis is generally poor, dependent on the tumor type, and a mean survival is generally measured in months, not years (mean 6–7 months).

Summary

Odontogenic and non-odontogenic tumors of the jaws are a relatively rare and heterogeneous group of benign and malignant neoplasms, hamartomas, and other bone-related lesions that demonstrate great variability in etiology, biologic behavior, and clinical significance. Ameloblastoma, keratinizing odontogenic tumor, giant cell lesions, fibrous dysplasia, and various sarcomas of bone are typically the most significant and commonly encountered for surgeons managing this diverse group of cellular proliferations. Treatment should be tailored for each individual patient based on tumor histology, size, and location, as well as a number of other patient-related conditions. In general, however, benign disease should be treated like benign disease and maxillomandibular continuity preserved whenever possible. Malignant tumors generally necessitate radical resection, often with adjuvant or neoadjuvant chemotherapy, radiation therapy, cervical lymphadenectomy, and immediate reconstruction with microvascular free tissue transfer.

Chapter 33

Mucosal Lesions (Potentially Malignant Disorders of the Oral Mucosa)

Takashi Fujibayashi

The first part of this chapter will cover the concept and histology of potentially malignant disorders of the oral mucosa including the grading of mucosal dysplasia. The next section will cover potentially malignant diseases of the oral mucosa including leukoplakia, erythroplakia, keratosis of the palate, oral submucous fibrosis, and oral lichen planus. The final part will cover the early detection and management of potentially malignant disorders of the oral mucosa.

Management, 699

Concept and histology of potentially malignant disorders of the oral mucosa

General concept of potentially malignant disorders of the oral mucosa

Many technical terms have been used in books or journals to describe oral premalignancies that may have a potential to transform into cancers of the oral

mucosa. These include “precancer”, “pre-malignant”, “precursor lesions”, “intraepithelial neoplasia”, and “potentially malignant”. The report from the World Health Organization (WHO) Collaborating Center¹ proposed that oral mucosal presentations recognized as precancerous can be classified in two major groups as precancerous lesions and precancerous conditions. A precancerous lesion was defined as “a morphologically altered tissue in which oral cancer is more likely to occur than in its apparently normal counterpart”. On the other hand, a precancerous condition was defined as “a generalized state associated with a significantly increased risk of cancer”. This classification was based on the concept that the origin of malignancy in the oral mucosa of a patient with a precancerous lesion would correspond with the specific local site of precancer; whereas a malignancy may arise in any part of the oral mucosa in a precancerous condition. This concept was generally accepted at the time when these terms were proposed.

Using this model, two precancerous lesions, leukoplakia and erythroplakia, were defined, and syphilis, sideropenic dysphagia, and oral submucous fibrosis were described as examples of precancerous conditions. Over a 20-year period this concept and classification had been used and quoted by many investigators and clinicians, and also discussed with regard to potential malignancy of the nominated and non-nominated oral lesions and conditions. As a result of this discussion, in 1997 the WHO modified the classification of precancerous lesions and precancerous conditions without altering the basic concept of two major groups of lesions and conditions.² Table 33.1 shows this clinical classification of precancerous lesions and precancerous conditions. Precancerous lesions include leukoplakia, erythroplakia, and palatal keratosis associated with reverse smoking, and precancerous conditions include sideropenic dysphagia, lichen planus, oral submucous fibrosis,

Table 33.1 Classification of precancerous lesions and conditions by WHO (1997).

Precancerous lesions	Precancerous conditions
Leukoplakia	Sideropenic dysphagia
Erythroplakia	Lichen planus
Palatal keratosis associated with reverse smoking	Oral submucous fibrosis
	Syphilis
	Discoid lupus erythematosus
	Xeroderma pigmentosum
	Epidermolysis bullosa

syphilis, discoid lupus erythematosus, xeroderma pigmentosum, and epidermolysis bullosa.

Many recent research reports of clinical studies on epidemiology, natural history, observation on malignant transformation rate, and investigations on morphological and cytological changes, chromosomal, genomic and molecular alterations suggest the need for some modification of the concept of precancerous lesions and conditions. It is now known that even clinically normal looking oral mucosa in patients with precancerous lesion on one side of the oral cavity may have dysplasia or molecular abnormality on the contralateral site, suggesting the possibility of malignant transformation, and that cancer could subsequently develop in the normal-appearing mucosa. A workshop coordinated by the WHO Collaborating Centre for Oral Cancer and Precancer in the UK was held in London in 2005, and the report of the workshop was subsequently published.³ The report recommended the term “potentially malignant disorders” to refer to precancer. Potentially malignant disorders of the oral mucosa are also indicators of risk of likely future malignancies elsewhere in clinically normal-appearing oral mucosa and not only site-specific predictors. Potentially malignant disorders of the oral mucosa include leukoplakia, erythroplakia, palatal lesions in reverse smokers, oral submucous fibrosis, actinic keratosis, lichen planus, discoid lupus erythematosus, and hereditary disorders with increased risk (Table 33.2).

Histology (grading of dysplasia)

Histological changes that may be observed in potentially malignant disorders of the oral mucosa can be

Table 33.2 Potentially malignant disorders of the oral mucosa agreed in an international working group coordinated by the WHO Collaborating Centre for Oral Cancer and Precancer in the UK (2005).

Potentially malignant disorders of the oral mucosa
Leukoplakia
Erythroplakia
Palatal lesions in reverse smokers
Oral submucous fibrosis
Actinic keratosis
Lichen planus
Discoid lupus erythematosus
Hereditary disorders with increased risk

expressed as oral epithelial dysplasia. Although the clinical appearance of oral epithelial dysplasia is variable, oral squamous malignancies of the lining mucosa are known generally to develop from dysplastic surface epithelium of the oral mucosa. Histological change that may contribute to a diagnosis of epithelial dysplasia was defined by the WHO as shown in Table 33.3.² The 13 items of histological change are a combination of features of both alterations of cell kinetics of the proliferative compartment and disturbed maturation toward keratinization of epithelial cells.

The grade of epithelial dysplasia can be expressed in several categories such as no dysplasia, mild dysplasia, moderate dysplasia, and severe dysplasia.^{1,2,4,5} The relationship of epithelial dysplasia in various grades to the subsequent development of cancer has not been fully clarified. However, it is generally believed that any degree of epithelial dysplasia, even a mild form, indicates an increased risk, and severe dysplasia suggests a very high risk of the subsequent development of cancer. Dysplasia is often seen coexisting with invasive carcinoma. It should be also noted that some cellular atypia, usually of a minor degree, is often present in inflammatory conditions. Severe grades of epithelial dysplasia may merge into the lesion customarily designated as carcinoma *in situ* (CIS), in which the whole, or almost the whole, thickness of squamous epithelium shows the cellular features of carcinoma without stromal invasion.²

Some attempts have been made to standardize the degree of dysplasia by providing weighted scores for the 13 microscopic features,⁴ but wide intra- and interobserver variability was encountered in grading oral epithelial dysplasia.⁵⁻⁷ Therefore, the thickness (height) of the cellular change was taken into account. In mild forms of dysplasia, recognizable changes are limited to the lower third of the epithelium; in moderate dysplasia they extend to the middle third; and in severe dysplasia, the changes extend to the upper layers.⁸ However, it was reported that the variation in the grading of dysplasia was still present even using

Table 33.3 Histological changes that may contribute to a diagnosis of epithelial dysplasia (WHO 1997).

Loss of polarity of the basal cells
The presence of more than one layer having a basaloid appearance
Increased nuclear–cytoplasmic ratio
Drop-shaped rete ridges
Irregular epithelial stratification
Increased number of mitotic figures
Mitotic figures that are abnormal in form
The presence of mitotic figures in the superficial half of the epithelium
Cellular and nuclear pleomorphism
Nuclear hyperchromatism
Enlarged nucleoli
Loss of intercellular adherence
Keratinization of single cells or cell groups in the prickle cell layer

the concept of depth of dysplasia.^{9,10} Knowledge of clinical information did not increase agreement rates between examiners.¹¹ Inflammation in the lesions further decreased agreement rates.¹²

In 2005 the WHO revised the criteria used for diagnosing oral epithelial dysplasia in epithelial precursor lesions from 13 to 16 items by classifying seven architectural and nine cytological criteria as shown in Table 33.4.¹³ They encouraged the use of a combination of architectural and cytological changes with more defined consideration of levels of change within the epithelium. When architectural disturbance is accompanied by cytological atypia, the term dysplasia applies.

Although dysplasia represents a spectrum and no criteria exist to divide this spectrum precisely into several grades, grading of oral epithelial dysplasia is still conventionally used.^{13,14} In this system, grade 1 (mild dysplasia) demonstrates general architectural disturbance limited to the lower third of the epithelium accompanied by cytological atypia (Fig. 33.1). Grade 2 (moderate dysplasia) demonstrates architec-

tural disturbance extending into the middle third of the epithelium (Fig. 33.2). Grade 3 (severe dysplasia) starts with greater than two thirds of the epithelium showing architectural disturbance with associated cytological atypia. However, architectural disturbance extending into the middle third of the epithelium with sufficient cytological atypia is upgraded from moderate to severe dysplasia (Fig. 33.3).

The term carcinoma *in situ* (CIS) denotes that malignant transformation has occurred but invasion is not present. It is not possible to recognize this morphologically. The following is recommended for the diagnosis of CIS: full-thickness or almost full-thickness architectural abnormalities in the viable cellular layers accompanied by pronounced cytological atypia (Fig. 33.4). Atypical mitotic figures, abnormal superficial mitoses, increased nuclear size, and anisonucleosis are often seen in CIS (Fig. 33.5).

Although the revised criteria of oral epithelial dysplasia of WHO (Table 33.4) describe accurate histological characters of the lesion, interobserver variability still occurs.¹⁵ Recently some reports

Table 33.4 Criteria used for diagnosing dysplasia (WHO 2005).

Architecture	Cytology
Irregular epithelial stratification	Abnormal variation in nuclear size (anisonucleosis)
Loss of polarity of basal cells	Abnormal variation in nuclear shape (nuclear pleomorphism)
Drop-shaped rete ridges	Abnormal variation in cell size (anisocytosis)
Increased number of mitotic figures	Abnormal variation in cell shape (cellular pleomorphism)
Abnormally superficial mitoses	Increased nuclear–cytoplasmic ratio
Premature keratinization in single cells (dyskeratosis)	Increased nuclear size
Keratin pearls within rete pegs	Atypical mitotic figures
	Increased number and size of nucleoli
	Hyperchromasia

Fig. 33.1 Mild dysplasia. There is hyperplasia of basal and parabasal cells with weak loss of polarity showing slightly increased nuclear size and increased nuclear:cytoplasmic ratio. The architectural changes are limited to the lower third of the epithelium.

Fig. 33.2 Moderate dysplasia. The epithelial cells demonstrate variation in nuclear size and shape with increased number and size of nucleoli with some disturbance in epithelial stratification and polarity of basal and parabasal cells. The architectural changes extend into the middle third of the epithelium.

Fig. 33.3 Severe dysplasia. The architectural disturbance with cytological atypia including loss of intercellular adhesion extends to more than two thirds of the epithelium.

Fig. 33.4 Carcinoma *in situ* (CIS). The full thickness of the epithelium shows architectural disturbances such as irregular epithelial stratification, irregular polarity of basal cells, drop-shaped rete ridges with cytological atypia of anisonucleosis, nuclear and cellular pleomorphism, and atypical mitotic figures.

Fig. 33.5 Carcinoma *in situ* (CIS). The epithelial cells demonstrate increased nuclear size, nuclear pleomorphism, and increased size of nucleoli.

demonstrated superiority of a new binary system of grading for predicting malignant transformation,¹⁶ in which the grade of dysplasia was classified into two categories: “low risk” with no dysplasia or mild dysplasia and “high risk” with moderate dysplasia or severe dysplasia, and this concept was supported by the working group.¹⁷ Some pathologists suggested the use of the term squamous intraepithelial neoplasia (SIN) which was originally used for the uterine cervical premalignant lesions, or variations on this such as oral intraepithelial neoplasia (OIN).¹⁸ This terminology is based on the concept that many of the potentially malignant disorders of oral mucosa are committed on a path to malignancy. According to the SIN system, mild dysplasia is regarded as SIN 1, moderate dysplasia as SIN 2, and both severe dysplasia and CIS as SIN 3.¹³ However, the SIN concept that all levels of dysplasia are actually different levels of neoplasia even if prior to invasion, is disputed.^{14,17} The histological findings of dysplasia therefore indicate no more than a lesion has a statistically increased

risk of malignant change; they cannot be used for confident prediction of malignant change in any individual case.¹⁹

Potential molecular biological markers or molecular genetics of potentially malignant disorders of the oral mucosa which may have special association with progression of oral epithelial dysplasia to carcinoma, have been studied.^{19–22} Loss of heterozygosity (LOH) at 3p and 9p increased the risk of progression of dysplasia to squamous cell carcinoma (SCC). Mutation of p53 tumor suppressor gene is one of the most common genetic events in carcinogenesis. Although LOH at the p53 loci appears to be associated with progression, mutation of the p53 gene is rare in dysplasia and appears to be a late event. The p53 protein and other markers of apoptosis appear in basal and parabasal layers of dysplastic lesions that progressed to SCC. The measurement of nuclear DNA (DNA ploidy) may have a prognostic value. While some studies found an association of aneuploid pattern with progression to SCC, others have found no such relationship. Matrix metalloproteinases (MMP)-1 and -9 were more commonly expressed in dysplastic tissue that progressed to SCC. Cytokeratin-4 (K4), K13, transglutaminase 3 (TG-3) were suppressed and expression of K14 and K17 was elevated in SCC and severe dysplasia. Epidermal growth factor receptor shows a linear increase in intensity of histochemical staining, suggesting an increase in dysregulation of epithelial cell proliferation with increasing degree of dysplasia. However, to date, no single definitive molecular marker to predict the progression of potentially malignant disorders of the oral mucosa to SCC has been identified.

Potentially malignant disorders of the oral mucosa

Leukoplakia

The most common and important potentially malignant disorder of the oral mucosa is leukoplakia. WHO¹ first defined leukoplakia as “a white patch or plaque that cannot be characterized clinically or pathologically as any other disease” and as a main part of oral precancerous lesions, which means it has an increased risk of malignant potential. This concept has been adapted and refined worldwide through several international seminars.^{2,13,23,24} The latest report of the working group³ further refined the description as: “The term leukoplakia should be used to recognize white plaques of questionable risk having excluded (other) known diseases or disorders that carry no increased risk for cancer.”

Leukoplakia must be differentially diagnosed from other known predominantly white lesions or disorders such as white sponge nevus, frictional keratosis, moscicatio buccarum, chemical injury, acute pseudomembranous candidosis, leukoedema, lichen

planus (plaque type), lichenoid reaction, discoid lupus erythematosus, skin graft, hairy leukoplakia, and leukokeratosis nicotina palate. Leukoplakia is a clinical term. At clinical examination a provisional diagnosis of leukoplakia is made if a predominantly white lesion cannot be clearly diagnosed as any of these other diseases. A biopsy is mandatory to exclude any of the other named diseases. A definitive diagnosis of leukoplakia can be made when any etiological cause, such as trauma, biting, chemicals other than tobacco/areca nut use, has been excluded and histopathology has not confirmed any other specific disorder. However, leukoplakia itself has no specific histology, it may show atrophy or hyperplasia (acanthosis), and may or may not demonstrate epithelial dysplasia.

Oral leukoplakia occurs most frequently on the lip vermillion, buccal mucosa, lateral border of tongue, floor of mouth, and gingival mucosa. The clinical finding of leukoplakia has been reported using various terms, but classification into two types is generally accepted: homogeneous and non-homogeneous leukoplakia.² The classification is based on surface color and morphologic characteristics. Homogeneous leukoplakias look uniformly flat and thin, and may

exhibit shallow cracks of the surface keratin (Figs 33.6 and 33.7). Non-homogeneous leukoplakias include several subtypes:

- speckled type – mixed appearance of white and red, but still retaining predominantly white character (Figs 33.8 and 33.9);
- nodular type – small polypoid outgrowths with rounded red or white excrescences;
- verrucous type – wrinkled or corrugated surface appearance.

In general terms, non-homogeneous leukoplakias present a greater risk of malignant change than the homogeneous types. However, the latest working group³ reported that these two categories were imprecise and of limited value. However, they also reported that it should be recognized that non-homogeneous type may include the following two distinct groups which have a higher risk of malignancy.

- Erythroleukoplakia is one type of non-homogeneous leukoplakias. It is very similar to speckled type leukoplakia and appears white and red, with red areas of minimal keratin production inter-

Fig. 33.6 Homogeneous leukoplakia in the lower gingival mucosa.

Fig. 33.8 Non-homogeneous leukoplakia (speckled type) on the lateral to ventral surface of the tongue.

Fig. 33.7 Histopathologic feature of homogeneous leukoplakia showing hyperorthokeratosis and acanthosis with no dysplasia.

Fig. 33.9 Histopathology of speckled type leukoplakia showing moderate epithelial dysplasia and severe round cell infiltration in the subepithelial connective tissue.

persed among the background of white areas with thickened keratin. The red areas of erythro-leukoplakia are larger than in speckled type leukoplakia, and erythroleukoplakia shows a rather thin epithelial layer with some dysplasia (Figs 33.10 and 33.11). An alternative term for this is erosive leukoplakia.

- Proliferative verrucous leukoplakia (PVL) is another type of oral leukoplakia. PVL develops nodular, papillary or verrucous surface projections (Figs 33.12 and 33.13), which gradually spread laterally to encompass large areas of oral mucosa. Sometimes it presents at multifocal sites in the same oral cavity.^{25–27} PVL occurs predominantly (74%) in females, unlike other leukoplakia, and 63% of patients did not use tobacco products.²⁸ In histology almost half of all PVL patients demonstrate epithelial dysplasia and more than 70% of them will develop SCC later.^{27–30} PVL is an aggressive form of oral leukoplakia with considerable morbidity and strong prediction for malignant transformation. Conservative management of these lesions has been unsuccessful and wide surgical excision offers the best hope for control.³¹

Malignant transformation rates from oral leukoplakia reported in the literature vary greatly from study to study.^{20,32} Table 33.5 shows a summary of major reports on this topic from various countries.^{25,33–45} In the large-scale community-based surveys in India, estimates of the malignant transformation rate range from 0.13–0.9%.^{33–35} In contrast, reports from hospital-based sample studies derived from patients referred to selected special units by primary health care workers show much higher rates, ranging widely between 1.8 and 17.5%.^{25,36–45} A study of pooled estimates reports that the prevalence rate of oral leukoplakia is 2.60% in the world population and that a global malignant transformation rate of oral leukoplakia is 1.36% per year.⁴⁶ In a general review performed by the latest workshop group³² for predicting malignant transformation in oral leukoplakia, older patients, particularly females, are more at risk than younger patients; the duration of the disorder may also be important. Those who have never used tobacco seem at greater risk than smokers. Tongue, floor of mouth, and retromolar/soft palate complex are more at risk. The non-homogeneous type develops malignancy far more frequently than the homogeneous

type. Large lesions covering several intraoral sites also appear more at risk.

Erythroplakia

Oral erythroplakia is defined as “a fiery red patch that cannot be characterized clinically or pathologically as any other definable lesion”.² The workshop group of 2005³ did not make any significant change to this definition. Erythroplakia is often flat with a smooth or granular surface, and numerous other red patches and/or macules that could arise on the oral mucosa should be excluded before considering erythroplakia. The differential diagnosis must include inflammatory and/or immune disorders such as desquamative gingivitis, erythematous lichen planus, discoid lupus erythematosus, pemphigoids, hypersensitivity reactions, Reiter’s disease, infections such as erythematous candidiasis and histoplasmosis, and hamartoma/neoplasms such as hemangiomas and Kaposi’s sarcoma.⁴⁷

Oral erythroplakia is a rather rare disease and the prevalence rate in the general population is in the range 0.02–0.83%.⁴⁷ The soft palate, the floor of the mouth, ventral surface of the tongue (Fig. 33.14), and the buccal mucosa in the middle-aged and the elderly are most commonly affected. The etiology and pathogenesis of oral erythroplakia are poorly understood, but it was suggested that tobacco and alcohol use are probably involved in most cases.

Erythroplakia is a clinical term, just like in leukoplakia, and it does not have any specific histopatho-

logical connotation. It may show superficially invasive carcinoma, CIS, severe dysplasia, or moderate to mild dysplasia (Fig. 33.15). Oral erythroplakia has the highest risk of malignant transformation compared to all other oral potentially malignant disorders – these red lesions often show invasive carcinoma and CIS or severe dysplasia.⁴⁸ Because of the limited number of clinical cases of oral erythroplakia and the fact that it is usually treated soon after diagnosis, the true malignant transformation rate of pure erythroplakia is unknown. Transformation rates of oral lesions histologically diagnosed as CIS or severe dysplasia, including cases of erythroplakia but also leukoplakia and erythroplakia, vary from 14–50%.⁴⁷

Fig. 33.14 Erythroplakia on the ventral surface of the tongue showing red, smooth, flat patch.

Fig. 33.15 Histopathologic findings of erythroplakia with severe dysplasia. The architectural disturbances include decreased epithelial layer, irregular epithelial stratification, irregular polarity of basal and parabasal cells with loss of intercellular adhesion and some cellular atypia.

Palatal lesions in reverse smokers

This disorder is observed in certain rural populations in the Indian subcontinent, New Guinea, and Amazon who smoke with the lighted end of homemade cigarettes and cigars inside the mouth. This habit leads to red, white or mixed lesions with very thick keratin build-up on the surface of the hard palate. This reverse smoking is linked to a very high rate of malignant transformation of the affected palatal mucosa where carcinoma seldom otherwise develops.³⁴

Oral submucous fibrosis

Oral submucous fibrosis (OSF) is a chronic disorder of the upper digestive tract including the oral cavity, oropharynx, and often the upper third of the esophagus, characterized by fibrosis of the mucosa. Clinical presentations in early forms include a burning sensation with exacerbation by spicy food, vesiculation or ulceration of oral mucosa, blanching of mucosa, and “leathery” mucosa which shows thickened, firm tissue with a wrinkled surface. Late forms present fibrous bands within the mucosa, limitation of mouth opening, difficulties with mastication and phonation, narrowing of the oropharyngeal orifice with distortion of the uvula, and “woody” changes to the mucosa and tongue.³ In histopathology, OSF shows epithelial atrophy, with metaplasia of non-keratinized areas to para- or ortho-keratinization, with various degrees of dysplasia. Thickening of the basement membrane is common, and there is marked reduction in vascularity of the connective tissues in inverse proportion to increased density of collagen, which appears hyalinized.⁴⁹

OSF has been reported mostly among subjects living in the Indian subcontinent, and neighboring Asian countries, who have a habit of chewing areca nut.⁵⁰ A clear dose-dependent relationship was observed for both frequency and duration of chewing areca nut in the development of OSF. The commer-

cially available freeze-dried products such as pan masala, guthka, and mawa (areca and lime) have high concentrates of areca nut per chew and appear to cause OSF more rapidly than self-prepared conventional betel quid.⁵¹ Areca alkaloids, such as arecoline and its active metabolite arecaidine, cause fibroblast proliferation and increase collagen synthesis. In addition, tannin present in areca nut reduces degradation of collagen by inhibiting collagenases; and the copper content in areca nut is high and copper is known to stimulate fibroblast proliferation. The areca nut may also induce the development of OSF by increased levels of cytokines such as interleukin (IL)-1, IL-6, transforming growth factor (TGF)-beta, platelet derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) in the lamina propria. Current evidence implicates collagen-related genes in susceptibility and pathogenesis of OSF.⁵¹

Epithelial dysplasia in OSF tissues appeared to vary from 7–26% depending on the population. Malignant transformation rate of OSF to oral cancer was reported as 7.6% by a long-term follow-up study of 17 years in India.⁵²

Oral lichen planus

Oral lichen planus (OLP) is one of the most prevalent diseases of the oral mucosa and can be found in every country of the world. Diagnosis of OLP should be based on both clinical features and histopathological findings that meet the diagnostic criteria of OLP.^{53,54} The most characteristic clinical feature of OLP is the presence of white striations and/or papules which often appear in bilateral areas of the oral mucosa (Fig. 33.16). These bilateral, often symmetrical reticular lesions are strong determining components of the clinical profile of OLP. In addition to the white lesions, erythematous lesions with plaque-type, atrophic, ulcerative or sometimes bullous appearance may also be observed during the course of the disease, but these red lesions are not OLP specific and

Fig. 33.16 Typical clinical feature of oral lichen planus (OLP) showing white striations with linear, reticular, and annular shapes in light erythematous or erosive background. This patient has bilateral symmetrical lesions.

can also be seen in other similar disorders. Essential histological criteria for diagnosing OLP are a band-like dense lymphoid cell infiltrate confined to subepithelial connective tissue and liquefaction degeneration of the epithelial basal layer. The epithelium may develop hyperkeratosis, atrophy, hyperplasia, acanthosis, and saw-toothed rete ridges (Fig. 33.17). There have been many discussions concerning atypical cytomorphology and dysplastic epithelial structure of the lesion clinically considered as OLP.^{55–60} The consensus has been that the histopathological diagnosis of OLP should be applied in the absence of epithelial dysplasia.

The criteria for diagnosing malignant transformation of OLP proposed by Krutchkoff *et al.*⁶¹ have also been generally agreed (Table 33.6). This has been confused by another discussion of differential diagnosis between true OLP (idiopathic OLP) and similar so-called oral lichenoid lesions (OLL)⁵⁷ which includes such lesions as oral lichenoid drug reactions (OLDR), oral lichenoid contact lesions (OLCL), oral lichenoid lesions in graft-versus-host disease (OLL-GVHD) (Figs 33.18, 33.19),⁶² and amalgam-associated oral lichenoid reactions (AAOLR).⁶³ Table 33.7 shows differential diagnostic criteria between OLP and OLL proposed by van der Meij and van der Waal.⁵⁷ In these criteria, absence of epithelial dysplasia is confirmed to diagnose OLP, and if either clinical or histopathological features are not obvious as OLP, the term OLL will be used.

Table 33.8 shows a summary of papers reporting malignant transformation rate in OLP from 1985 to the present, where the study involved more than 500 OLP patients.^{64–73} The malignant transformation rate varies from 0.4–6.4% in the observed period and 0.07–0.74% per year. Patients with OLL may have an increased risk of developing malignancies compared with patients with OLP.^{59,60} Some of the reports listed in Table 33.8 may include OLL patients among patients reported as OLP when the differential diagnosis of OLP and OLL had not been well discussed.

Fig. 33.17 Histopathologic findings of oral lichen planus (OLP). The dense band-like zonal cellular infiltration of lymphocytes with some macrophages is evident just under the epithelial tissue. The epithelium shows acanthosis with a little hyperparakeratosis, liquefaction degeneration in the basal cell layer, and some saw-tooth rete ridges, but no dysplasia.

Fig. 33.18 Oral lichenoid lesion in graft-versus-host disease (OLL-GVHD) in a bone marrow transplanted patient. Clinical features are quite similar to those of OLP.

Table 33.6 Criteria for diagnosing as malignant transformation of oral lichen planus (OLP) (from Krutchkoff *et al.* 1978).⁶¹

Original diagnosis
The diagnosis of OLP must have been properly verified with acceptable histopathologic evidence demonstrating at least two of the following four features: 1. Hyperkeratosis or parakeratosis (this is not necessary in the case of erosive OLP) 2. Saw-toothed rete pegs 3. Superficial infiltrate of lymphocytes 4. Basal cell liquefaction
History and follow-up
1. Clinical and historical features of alleged transformations must been adequately described. Information such as age, sex, precise location, and clinical description of the lesion are necessary 2. Reported transformations should have had proper follow-up (at least 2 years), with all changes in clinical features properly recorded
Tobacco exposure
Tobacco habits should have been properly documented to help distinguish between true malignant transformations and conventional carcinomas occurring in the mouths of patients who happen to have OLP

Fig. 33.19 Histopathologic findings of oral lichenoid lesion in graft-versus-host disease (OLL-GVHD). Dense lymphocyte infiltration with small number of granulocytes is observed from upper to lower connective tissues. The epithelium has flat rete ridges with slight dysplasia. These findings are histopathologically compatible with OLP. Histopathology alone cannot reliably distinguish between OLP and OLL.

Table 33.7 The differential diagnostic criteria between oral lichen planus (OLP) and oral lichenoid lesions (OLL) proposed by van der Meij and van der Waal (2003).⁵⁷

Clinical criteria

- Presence of bilateral, more or less symmetrical lesions
- Presence of a lace-like network of slightly raised gray-white lines (reticular pattern)
- Erosive, atrophic, bulbous and plaque-type lesions are only accepted as a subtype in the presence of reticular lesions elsewhere in the oral mucosa

In all other lesions that resemble OLP but do not complete the aforementioned criteria the term “clinically compatible with” should be used

Histopathological criteria

- Presence of a well-defined band-like zone of cellular infiltration that is confined to the superficial part of the connective tissue, consisting mainly of lymphocytes
- Signs of “liquefaction degeneration” in the basal cell layer
- Absence of epithelial dysplasia

When the histopathological features are less obvious, the term “histopathologically compatible with” should be used

Final diagnosis OLP or OLL

To achieve a final diagnosis clinical as well as histopathological criteria should be included

OLP: A diagnosis of OLP requires fulfillment of both clinical and histopathological criteria

OLL: The term OLL will be used under the following conditions:

1. Clinically typical of OLP but histopathologically only “compatible with” OLP,
2. Histopathologically typical of OLP but clinically only “compatible with” OLP,
3. Clinically “compatible with” OLP and histopathologically “compatible with” OLP

Table 33.8 Reported malignant transformation rate in oral lichen planus patients from 1985 to the present (studies involving more than 500 OLP patients).

Mignogna <i>et al.</i> ⁷³	2007	Italy	700	16.0	45/700	6.4	0.40	73

However, the report by Mignogna *et al.*⁷³ showing the highest rate of malignant transformation did not include OLL patients. Therefore, the malignant potential of OLP still remains controversial. WHO³¹ recommends that until distinct clinical and histopathological criteria have been developed on how to differentiate OLP from OLL, both lesions have to be considered as at risk for malignant transformation. The report of the 4th World Workshop on Oral Medicine (WWOM)⁶² also concluded that there is no consensus about the possible premalignant character of OLP at present; nevertheless, monitoring is recommended at least annually.

Others

Actinic keratosis of the lip is considered to be a potentially malignant condition. The squamous epithelium of the vermilion of the lip may be atrophic or hyperplastic with disordered maturation showing varying degrees of keratinization, atypia, and increased mitosis.

Discoid lupus erythematosus (DLE) sometimes shows very similar features to OLP. Clinical distinction of DLE from OLP and erythroplakia can be difficult. Malignant transformation has been reported when DLE affects the lip.

Hereditary disorders with increased risk are dyskeratosis congenita and epidermolysis bullosa. Dyskeratosis congenita (DC) is an inherited bone marrow failure syndrome that is characterized by lacey reticular hyperpigmentation of the skin, dystrophic nails, mucous membrane hyperkeratosis, and pancytopenia.⁷⁴ Oral white plaques in DC may be confused with leukoplakia. Development of SCC

from the lesion on the dorsum of the tongue at a very young age has been reported with a rather high incidence in DC patients.

Epidermolysis bullosa is a rare genetic disease characterized by cutaneous and mucosal blistering associated with subsequent scarring in response to minor trauma. Oral hyperkeratosis and SCC have been reported in association with epidermolysis bullosa.

Early detection and management of potentially malignant disorders of the oral mucosa

Early detection and diagnosis

The potentially malignant disorders (PMD) of the oral mucosa can arise not only from preceding lesions but also from any part of normal-looking mucosa^{3,75} and most PMD must be confirmed by histopathological diagnosis. The clinical diagnosis confirmed by histopathological diagnosis by scalpel biopsy is the gold standard for any PMD. Several diagnostic aids and adjunctive techniques for screening of patients for PMD and oral cancers have been developed recently.⁷⁶ Table 33.9 gives a summary of these examination methods and adjunctive techniques.

Conventional oral examination

A conventional oral examination under normal light by inspection and palpation is the standard method for screening PMD or oral cancers. The diagnostic ability of examination methods can be evaluated in

Table 33.9 Examination methods and adjunctives of diagnosing potentially malignant disorders or cancers of the oral mucosa.

Examination methods and adjunctive techniques	Material	Normal mucosa	Dysplasia (atypia)
Conventional oral examination	Inspection and palpation	Normal looking	Some abnormality
Vital staining:			
Toluidine blue	Tolonium chloride	No staining	Pale or dark royal blue
Iodine	Iodine glycerol or Lugol's solution	Dark (parakeratotic cell)	No staining
Tissue reflectance light visualization:			
ViziLite Plus®	Chemiluminescent light	Light bluish	Reflect and shine white
MicroLux DL	Battery-powered light	Light bluish	Reflect and shine white
Fluorescence imaging and spectroscopy:			
VELscope®	Handpiece-emitted blue light	Fluorescent glow	Loss of fluorescence
Brush cytology:			
OralCDx®	Cytology by brush biopsy	Negative (normal)	Atypical (abnormal), Positive (dysplasia/ca)
Scalpel biopsy:			
Incisional	Incisional biopsy for diagnosis	Normal tissue	Dysplasia or cancer
Excisional	Diagnosis and treatment		

terms of sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of diagnostic examination as shown in Table 33.10. Conventional oral examination is performed without using any specific device, but the detection of PMD depends on the skill of each examiner which differs with experience and knowledge. A review of this subject showed an overall sensitivity of 85% and specificity of 97% in conventional oral examination by general dentists when compared with the result of examination by an oral medicine specialist considered as a “true” clinical diagnosis.⁷⁷ This indicates the ability of an oral examination as a screening test in detecting lesions of the oral mucosa but does not necessarily mean making the correct diagnosis of the lesion.

Vital staining

Toluidine blue is a vital staining dye, which is also known as tolonium chloride, and it may stain nucleic acids and some abnormal tissues. The nuclear uptake of the dye in malignant lesions is consistent with the high density of nuclear material in neoplastic cells which shows a dark royal blue color, whereas non-malignant lesions such as inflammatory granulation tissues may show pale blue.⁷⁸ Toluidine blue is commercially available as a ready-to-use kit (OraScan®) comprising 1% toluidine blue as the staining rinse and 1% acetic acid for use as both pre- and postrinses. The efficacy of using this product was reported as high (100% in sensitivity) in detecting oral cancers but rather low (62% in specificity) in discriminating benign lesions.⁷⁹ The overall sensitivity and specificity of the test for detecting PMD (dysplasia) was only 74% and 66%, respectively. Therefore, toluidine blue appears to be good at detecting cancers but is positive in only two thirds of lesions with dysplasia. In addition, it may stain common, benign conditions such as non-specific ulcers. TBlue^{630®} is another product containing 0.5% toluidine blue in the swab which is used in combination with ViziLite® Plus.

Iodine vital staining can be also used for detecting PMD or oral cancers by applying Lugol’s iodine solution or iodine glycerol solution. Iodine can bind cytoplasmic glycogen of the oral mucosal epithelium,

and normal oral mucosa with parakeratosis will stain dark brown, but dysplastic or cancer cells will be poorly stained or unstained by loss of glycogen in their cytoplasm. The sensitivity and specificity in detecting oral dysplastic or malignant lesions was reported as 87.5% and 84.2%, respectively.⁸⁰ Iodine vital staining is difficult to apply to keratinized oral mucosa such as hard palate and gingiva where glycogen content is much decreased. A combination of toluidine blue staining and iodine staining is also possible.

Tissue reflectance light visualization

Tissue reflectance light visualization has been advocated for detecting PMD or oral cancers. Light system products are commercially available. ViziLite Plus® uses a disposable chemiluminescent light packet, while the MicroLux unit offers a battery-powered light. Normal oral epithelium absorbs the illuminated light, while a dysplastic lesion with abnormal cells reflects the light and shines clear white because of increased nuclear:cytoplasmic ratio in the non-keratinized oral mucosa. This visualization may enhance brightness and sharpness of white lesions and lesions with both red and white, but it was reported not to improve visualization of red lesions.⁸¹ However, a recent study of screening oral examination using 100 consecutive patients showed that an acetic acid rinse may have some benefit in making mucosal changes more visible, but it also showed that the chemiluminescent light visualization was no better than conventional oral examination in detecting diagnosable lesions.⁸²

Fluorescence imaging

VELscope® is a portable device which has been developed to visualize the fluorescence alteration in PMD and oral cancers. This unit emits blue light of 400–460 nm through the handpiece into the oral cavity; the light penetrates the oral mucosa from the surface of the epithelium through to the basement membrane. Normal tissue produces fluorescence and appears as an apple-green glow, while dysplastic epithelium and underlying stromal disruption cause loss of fluo-

Table 33.10 Concept of diagnostic accuracy of the examination method in diagnosing the disease.

	Disease present	Disease absent
Diagnostic examination positive	True positive (TP)	False positive (FP)
Diagnostic examination negative	False negative (FN)	True negative (TN)
Sensitivity of the diagnostic examination (%) = $TP \times 100 / (TP + FN)$		
Specificity of the diagnostic examination (%) = $TN \times 100 / (FP + TN)$		
Positive predictive value (PPV) (%) = $TP \times 100 / (TP + FP)$		
Negative predictive value (NPV) (%) = $TN \times 100 / (TN + FN)$		
Accuracy of the diagnostic examination (%) = $(TP + TN) \times 100 / (TP + FP + FN + TN)$		

rescence and appear dark by comparison to the surrounding normal mucosa. The efficacy of the device in detecting dysplasia or carcinoma which was confirmed in histopathology by scalpel biopsy has been reported with a rather small number of patients.⁸³ The fluorescence is absorbed by hemoglobin so any vascularity will appear dark. Further extensive investigation will be required to confirm the usefulness of this device.

Brush cytology

Oral exfoliative cytology has been used for many years with some criticism as not presenting adequate and reliable results. A new technology of brush cytology named OralCDx[®] BrushTest[™], taking a transepithelial sample with a specially designed brush (Fig. 33.20) and diagnosis by computerized analysis in the laboratory (CDx Laboratories, Inc.) has been developed recently. The computer assists in search for and identification of abnormal cells, which are then visually assessed by the pathologist, and the result of the specimen is put into the following categories; “negative”: no epithelial abnormality; “atypical”: abnormal epithelial changes of uncertain diagnostic significance; “positive”: definitive cellular evidence of epithelial dysplasia or carcinoma.⁸⁴ This is a potential oral cancer case-finding device, and when an abnormal result is reported as atypical or positive then it must be followed by a scalpel biopsy to obtain a definitive diagnosis. The sensitivity and specificity of the OralCDx technique were reported as 92.3% and 94.3% respectively, in detecting dysplasia or carcinoma when both brush and scalpel biopsies were performed on all 96 lesions in 80 patients.⁸⁵

Scalpel biopsy

Histological diagnosis made by taking a sample tissue material from the lesion by means of a scalpel biopsy is still considered the gold standard for definitive diagnosis. However, the scalpel biopsy is a more invasive technology which can only be applied to a

limited number of sites at the same time. A method of “microbiopsy” by scraping the whole layer of epithelial tissue using a disposable dermatological curette to cause slight bleeding has been reported recently.⁸⁶ This microbiopsy can be applicable to PMD in the presence of multiple lesions such as in proliferative verrucous leukoplakia or oral lichen planus which may require repeated histological assessment to detect any dysplastic or malignant changes. Although a similar accuracy to scalpel biopsy in diagnosis by microbiopsy has been reported, the reduced dimensions of the microbiopsy samples and their lack of orientation suggest some disadvantages in recognizing the invasiveness of the lesion across the basement membrane.

A scalpel biopsy should be performed in cases of dysplasia to avoid false-negative results in cases of carcinoma. There are two methods for scalpel biopsy: incisional and excisional. An incisional biopsy is performed by taking a small piece of tissue sample with a scalpel for the purpose of making the definitive diagnosis. In the biopsy of PMD, the most malignancy-suspected part of the lesion, such as indurated, erosive, ulcerative, verrucous, or red areas, rather than a white area, is the preferred site to perform the biopsy. Vital staining by toluidine blue or iodine may help to define the most malignancy-suspected site of the PMD. If the lesion has a homogeneous appearance a marginal area of the lesion, including a normal-looking area, is a preferred site to make the incision. On the other hand, an excisional biopsy is performed to remove the whole area of the lesion for both treatment and definitive diagnosis (Figs 33.21–33.24). Therefore, it is indicated for smaller lesions, and the excision line must be placed outside the lesion, including peripheral normal mucosa.

Management

The main concept of the management of PMD is to avoid malignant transformation. As the most common PMD encountered in clinical practice is oral leukoplakia, the major focus of management of PMD

Fig. 33.20 A kit for brush biopsy.

Fig. 33.21 The lateral surface of the tongue showing white and red lesion. Clinical diagnosis was a non-homogeneous leukoplakia (speckled type).

Fig. 33.22 Excisional biopsy was performed with scalpel, including the whole area of the lesion.

Fig. 33.23 Excised tissue, 20 × 17 mm in dimensions.

Fig. 33.24 Histopathological findings showed early invasive squamous cell carcinoma in the central part (b in high power field view) with acanthosis and hyperkeratosis in the periphery (a in low power field view).

can be considered to be that of leukoplakia. The management of other PMD can be modified according to the biological nature of each PMD and the histopathological characteristics of each PMD, including the degree of epithelial dysplasia.

The report by the latest workshop group of WHO (2005) on the consensus view on the management of PMD mainly focused on oral leukoplakia.⁸⁷ There are several protocols for the management of PMD: surgical treatment, such as excision by scalpel, electrosurgery (Figs 33.25–33.28), laser surgery; medical treatment with systemic or local chemopreventive agents such as vitamin A, retinoids, beta carotene, lycopene or some other topical ointments; cessation of risk activities such as tobacco, alcohol; “wait and see” policy under strict clinical and histological surveillance with frequent clinic visits and examinations including vital staining, tissue reflectance light visualization, fluorescence imaging, brush cytology, and scalpel biopsies if necessary.

Among these options, surgical removal is generally considered to be the recommended first choice and the most reliable way of management of PMD, especially for lesions with high malignant potential such as erythroplakia, proliferative verrucous leuko-

Fig. 33.25 A homogeneous leukoplakia on the lateral side of the tongue.

Fig. 33.26 Excisional biopsy was performed using an electro-surgical unit. (a) Excised tissue. (b) Surgical wound.

plakia, erythroleukoplakia, speckled type leukoplakia, palatal lesions in reverse smokers, and oral submucous fibrosis. The hypothesis that removing PMD by active surgical intervention (either scalpel or laser) can prevent the onset of oral cancer, remains unproved, however, and it is also considered reasonable that more conservative treatments or “wait and see” policy are options if the lesion is considered to have low malignant potential. The report of the 4th WWOM recommends the use of topical corticosteroids as the first-line treatment for oral lichen planus

Fig. 33.27 Histopathological findings of tissue from Fig. 33.26(a) showing hyperparakeratosis and acanthosis without dysplasia.

Fig. 33.28 The surgical site from Fig. 33.26(b) has a normal appearance 1 year after the surgery.

(without dysplasia) and systemic corticosteroids for severe, widespread oral lichen planus.⁶² A report of long-term treatment outcome of PMD (leukoplakia and erythroplakia) in 236 patients in Denmark indicated that clinical types of leukoplakia (homogeneous or non-homogeneous) and the size of the lesion (exceeding 200 mm² or not) showed increased risk, but no other variables such as epithelial dysplasia, site and surgical intervention (surgical removal or not) showed statistically significant risk for malignant development by logistic regression analysis.⁴¹ However, most reported observational studies may have selection bias. It is possible that lesions considered at higher risk had a greater likelihood of being actively treated, whereas lesions with a less troubling clinical appearance may have been more likely to be selected for surveillance only.⁸⁷

Although removal of the PMD seems to be the predominant method of treatment, no definitive randomized controlled clinical trials have been undertaken. As for laser surgery, the CO₂ laser, NdYAG laser, and KTP laser have been employed for excision or vaporization for the treatment of PMD, especially oral leukoplakia. The main advantages of laser sur-

gery are the hemostatic effects, limited tissue contraction and scarring after therapy, reduced postoperative pain, swelling, and infection. These advantages may permit the treatment of large or multiple lesions. Vaporization does not provide a tissue specimen for histological diagnosis, which is a major disadvantage in laser vaporization procedures.⁸⁸ Cryosurgery does not seem to be of particular benefit in the management of leukoplakia: recurrence rates of 20–71.4% and malignant transformation rates of 7–25% are reported.

Surgical excision of PMD offers significant advantages over laser vaporization. The most important advantage is that excision generates a surgical specimen that provides the patient and surgeon with histological evidence of the entire lesion upon which to base future treatment planning.⁸⁹ However, the report of the 4th WWOM²¹ summarized from a systematic literature review that it is not possible to offer evidence-based recommendations for specific surgical (scalpel or lasers) or non-surgical (medical) interventions of dysplastic oral lesions due to the lack of randomized clinical trials at present. If further investigations can identify specific molecules associated with malignant progression, these could possibly serve as therapeutic targets for future management strategies of PMD.

Chapter 34

Principles of Oral Cancer Management

Brian L. Schmidt

This chapter presents the reader with the principles of oral cancer management. The focus of the chapter will be the comprehensive evaluation and treatment of the oral cancer patient. Oral cancer management should be patient focused, evidence based and surgeon driven. Oral squamous cell carcinoma (SCC), which comprises 95% of oral cancers, is a surgical disease. Oral cavity carcinoma has peculiar biologic and capricious clinical behavior relative to other head and neck sites. The recommendations for treatment are based on the available literature. Few studies focus specifically on oral cavity carcinoma and most published information has come from studies which include other head and neck sites (i.e. oropharyngeal, hypopharyngeal, and laryngeal). A comprehensive understanding of the relevant literature, as well as its shortcomings, is requisite. Moreover, the surgical oncologist specializing in oral cavity carcinoma must have a working and intimate knowledge of the indications, toxicity, and efficacy of adjuvant therapy.

Non-resectable SCC or poor surgical candidates, 727

Summary, 727

Epidemiology and risk factors

The incidence of oral squamous cell carcinoma, particularly in younger patients, is increasing in North America and the UK.^{1,2} In certain regions of the world, such as India, oral cancer is one of the most common malignancies. In these regions of the world the use of betel nut and betel quid clearly contribute to the high incidence of oral cancer. However, the etiology, outside of tobacco and alcohol use, in the western portions of the world is less clear. Survival rates for oral cancer patients have not changed significantly. Survival for young patients with oral SCC has been equivocal with early studies showing poorer

survival³ and more recent studies showing improved survival.⁴ The roles of tobacco and alcohol are firmly established as risk factors for oral cancer. However, Schmidt *et al.* demonstrated that approximately 33% of oral squamous cell carcinoma patients were never smokers.⁵ Our understanding of the role of smokeless tobacco in oral carcinogenesis has gone through considerable evolution over the last three decades. The conclusion of a recent review of 32 relevant studies published between 1920 and 2005 concluded that smokeless tobacco, at most, plays only a minor role in the development of oral cancer.⁶ A facile, but erroneous, explanation for the increase in oral cancer rates with younger patients has been human papilloma

virus (HPV). There has been considerable confusion regarding the role of HPV in the development of oral cancer. When evaluating studies addressing the role of HPV in head and neck cancer it is important to consider the method of sample collection as well as the assay used to measure HPV. Based on the available studies there is a lack of reproducible molecular data supporting the role of HPV in the development of oral cancer.⁷ A multicenter case-control study of 1415 cases of oral cavity cancer detected HPV DNA in only 3.9% of biopsy specimens.^{7,8} This is in contrast to oropharyngeal carcinogenesis where HPV has a much stronger etiologic role.^{7,8}

Histologic grading, tumor staging, and clinical behavior

Ninety-five percent of oral cancers are squamous cell carcinoma (SCC). Different histologic variants of SCC include verrucous SCC, basaloid SCC, and papillary SCC (Fig. 34.1). Clinicians and investigators have attempted to use the combination of clinical information and histologic findings to predict the behavior of oral SCC. The histologic features that have been evaluated include tumor differentiation, tumor thickness, tumor size, and tumor invasive pattern.

Tumor differentiation

Broders' grading system categorizes carcinomas into well, moderately, and poorly differentiated; however, there is little evidence that tumor grading is of value in predicting metastasis or managing oral SCC.⁹ While Byers *et al.* demonstrated a significant association between tongue SCC tumor grade and metastasis, a significant limitation of this study is that the authors did not analyze the clinically negative nodes in the patients with T1 and T2 lesions.¹⁰ A more recent study of 71 patients with SCC of the oral tongue evaluated the Anneroth grading system, the Bryne grading system, and the Martinez-Gimeno grading system, as well as stage, perineural invasion, vascular invasion, lymphovascular invasion, shape, stage, growth pattern, and thickness.¹¹ After careful analy-

Fig. 34.1 Histologic variants of oral squamous cell carcinoma. Papillary SCC (left) shows mild degrees of atypia with invasive islands seen in the lamina propria. Verrucous carcinoma (center) is characterized by proliferation with broad, deeply pushing epithelial rete with parakeratin plugging and no atypia. Basaloid SCC (right) demonstrates islands of invasive, basaloid appearing malignant epithelial cells with palisading peripheral cells and comedo (central) necrosis.

sis, only tumor thickness was an independent risk factor for nodal metastasis. This study demonstrated no association between tumor grade and subclinical nodal metastasis.

Modified versions of the grading system have been published by Anneroth *et al.*¹²⁻¹⁴ This grading system includes several factors including degree of keratinization, nuclear polymorphism, number of mitoses per high power field, pattern of invasion, and lymphoplasmacytic infiltration. Other factors that have been studied include, but are not limited to, tumor shape (reductive or expansive), growth pattern (endophytic or exophytic), perineural invasion, vascular invasion, muscular invasion, and depth of invasion. Kademani *et al.*, using the Anneroth malignancy grading system with modifications by Woolgar *et al.*, found in a series of 215 patients that this grading system was predictive both of disease-free survival as well as neck metastasis in oral SCC.¹⁵ Overall, tumor grading has not been shown to be a reliable predictor of outcome or metastasis.

Tumor thickness

Similar to the significant predictive value of tumor thickness with malignant melanoma, investigators have studied tumor thickness in oral cancer to determine whether thickness can be used to predict cervical metastasis. In 1970, Breslow demonstrated that tumor thickness is a primary predictive variable with malignant melanoma.¹⁶ For oral SCC tumor thickness is the only factor that has consistently shown promise as an indicator of risk for occult nodal metastasis; however, the recommended thickness cutoff for prescribing elective neck treatment based on the rate of metastasis varies greatly in the literature and ranges from 1.5–8 mm.^{11,14,17-23} Mohit-Tabatabai *et al.* retrospectively reviewed 84 cases of patients with floor of the mouth SCC and found that when patients had tumor thickness less than 1.5 mm the incidence of cervical metastasis was 1.8%. Tumor thickness greater than 1.5 mm was associated with a cervical metastasis rate of 48%.²³ Spiro *et al.* retrospectively evaluated 105 patients with either tongue or floor of the mouth SCC and found that 2 mm or less of thickness carried a metastasis rate of 7.5% while greater than 2 mm thickness carried a metastasis rate of 38%.²² Byers *et al.* evaluated 91 tongue SCC patients to determine whether preoperative or intraoperative factors including thickness of the specimen, depth of muscle invasion, frozen margin status, perineural invasion, vascular invasion, lymphatic invasion, histologic differentiation, or DNA ploidy could be used to predict lymph node metastasis.¹⁰ In this study the best predictors for nodal metastasis were greater than 4 mm of muscle invasion, double DNA ploidy and histologic differentiation.¹⁰ The DNA ploidy results agree with other studies demonstrating a weak correlation between DNA ploidy status and cervical metastasis in tongue SCC patients.²⁴

Studies which have evaluated tumor thickness highlight some of the pragmatic problems with using tumor thickness as a risk index. The first practical problem is the manner in which tumor thickness is measured. Some studies measured the entire thickness of the carcinoma from the surface of the carcinoma to the deepest point of invasion. Others advocated a “reconstructed” thickness, measuring from a line that approximates the boundary of where the normal mucosa would be to the deepest extent of the tumor. Other approaches focus on depth of invasion, only measuring from the basement membrane to the deepest extent of tumor. The variability in techniques likely contributes to the wide range of thickness cutoff values in the literature that are associated with metastasis.

The second practical problem is one of sampling and how to best determine tumor thickness. All of the studies are retrospective and the majority used paraffin fixed sections from the primary tumor specimen to determine thickness. With this approach, the pathologist has the ability to first grossly examine the entire tumor *ex vivo* and identify the portion containing the deepest extent of invasion. However, the decision to electively treat the neck is generally based on an incisional biopsy before surgical resection and pathologic evaluation of the primary tumor. Therefore, the measured thickness obtained from the incisional biopsy will often be an underestimation of the true maximal tumor thickness. Therefore, applying the measurements based on the incisional biopsy alone will often lead to undertreatment of the neck. Another problem with using recommended cutoffs for tumor thickness is that the majority of studies addressing tumor thickness are based on the argument that failure rates up to 20% are an acceptable risk. Whether this risk is truly acceptable depends on the surgeon and, more importantly, on the patient. Warburton *et al.* approached their determination of a thickness cutoff differently. They attempted to find a point where both the sensitivity and specificity for predicting neck metastasis were maximized. They settled on a threshold of tumor thickness of 2.2 mm which yielded a sensitivity and specificity of 87.5% and 78.9% respectively.¹⁸ Although this is likely one of the most objective ways of creating a useful risk measurement tool, their cutoff at 2.2 mm is small enough to make use of this cutoff value problematic to execute in a clinical practice. A thickness of 2.2 mm would include all but the most superficial T1 tumors.²⁰

Tumor size and staging

The American Joint Commission on Cancer (AJCC) TNM staging protocol must be used to stage all patients with oral cancer.²⁵ Staging is an informative and critical step in determining a patient’s prognosis, as well as a critical administrative process requisite for quality research. There is some debate on the

accuracy of the current staging system for prognosticating, especially with regard to predicting nodal metastasis. Higher stage tumors have been correlated with higher rates of positive margins on resection, higher rates of local recurrence, and lower 5-year survival rates.²⁶ Bell *et al.* have shown that prognosis depends on stage.²⁷ Though advanced stage is used to predict risk of occult metastasis, multivariate analyses have shown that stage is not an independent risk factor for neck involvement when tumor thickness has been factored out.^{11,28} The surgical oncologist must keep in mind that even T1 tongue SCCs are associated with a significant rate (greater than 20%) of cervical metastasis.^{29–35} Management of the neck in patients with oral SCC is discussed more thoroughly later in the chapter. The AJCC system has been criticized for its simplicity. The system is based on surface diameter and excludes other factors that may play a larger role, such as perineural invasion, depth of tumor invasion, and the histopathologic features of the invasive front. Despite this, the simplicity of using the superficial diameter of a lesion as a prognostic tool, especially considering that it is likely to have some relationship to tumor thickness, still makes staging a frequently used measure that is the current standard of care.

Tumor invasive pattern

Relative to tumor thickness there is little information in the literature on the correlation between the tumor invasive pattern and the rate of metastasis; however, the different patterns of tumor invasion have been shown to have varying metastasis rates.^{36,37} SCCs that infiltrate along a broad front are much less likely to metastasize than SCCs comprised of separate packets of invading cells. Woolgar *et al.* have concluded that the pattern of invasion affects the interpretation of margins and even a clear (i.e. 5 mm) margin might be inadequate in the setting of widely separated clusters of invading tumor cells.³⁸ Despite these studies, an evaluation of invasive pattern is generally not used in clinical practice to guide treatment.

Perineural invasion

Some oral SCCs are neurotrophic and expression of nerve cell adhesion molecule (NCAM) on the SCC is associated with perineural invasion.^{39,40} While most studies have demonstrated that perineural invasion is a histopathologic feature that correlates with increased local recurrence and cervical metastasis,^{41–44} perineural invasion has also been shown not to correlate with metastasis. The presence of perineural invasion has been recommended as a potential indication for postoperative radiation therapy. However, the presence of perineural invasion should be considered in the setting of other features, e.g. margin status and lymph node involvement. In some cases perineural invasion can be identified using an

MRI. If perineural invasion is suspected based on preoperative MRI then care should be taken at the time of the operation to obtain a wide margin. Intraoperative frozen margin analysis of the nerve should be used to guide the extent of resection. The use of perineural invasion as an independent factor to predict prognosis and recommend treatment is unclear at this time.

Proliferative verrucous leukoplakia

Most oral SCCs are preceded by clinically evident precancerous oral lesions, including oral epithelial dysplasia, which appear as white (leukoplakia) or red patches (erythroplakia) that are characterized microscopically by varying degrees of dysplasia (from mild to severe).⁴⁵ Other oral SCCs are preceded by proliferative verrucous leukoplakia (PVL), a condition which is persistent, recurrent, and multifocal. Dysplasia has an unpredictable transformation rate to oral SCC that is thought to be approximately 16%,⁴⁶ whereas the transformation rate for PVL is much higher (50–70%).⁴⁷ PVL is a preneoplastic lesion that is recognized for its extremely high recurrence rate following surgical excision, its multifocal development, and its relentless progression to lesions of increasing severity (Fig. 34.2).^{47,48} PVL was first described in 1985 by Hansen.⁴⁸ In contrast to oral dysplasia, PVL is not associated with tobacco or alcohol consumption. In addition, whereas dysplasia is more common in men, the female to male ratio for PVL is about 4 to 1.^{47,48} At initial presentation, PVL lesions are white, irregular areas on the attached gingiva, buccal mucosa, and tongue. Histologically, PVL exhibits no dysplasia or mild dysplasia.⁴⁸ In spite of the bland clinical and histologic appearance of early lesions, PVL is characterized by relentless growth

and irreversible progression through a continuum of lesions, namely, hyperkeratosis, verruciform hyperkeratosis, verrucous hyperplasia, verrucous carcinoma, and ultimately SCC (Fig. 34.3). Repeated surgical excisions of all clinically and histologically appearing abnormal tissue can slow the transformation to carcinoma. However, such treatment results in significant disfigurement and morbidity. Moreover, surgical treatment does not halt the eventual progression to carcinoma.^{47–49} Despite studies which have evaluated the role of HPV, Epstein-Barr virus, p53 expression, transforming growth factor α , *Candida albicans*, and DNA ploidy, the cause of PVL is not known.^{50–55}

Preoperative assessment, staging, and work-up

The work-up of the oral cancer patient begins with a comprehensive history and physical examination. The pathology report should be reviewed to confirm the diagnosis. The histopathology slides should be reviewed by a pathologist with whom the surgeon works closely within their institution. A detailed, well performed history and physical examination can be used to understand the clinical behavior of the oral cancer. Oral cancers are a heterogeneous group and display capricious clinical behavior. Some understanding of the clinical behavior of an oral cancer can be gained by reviewing the history of the cancer and asking the following questions: when was the lesion first noticed, are there any associated symptoms (ear pain, swallowing difficulty, speech problems, limitation of tongue movement), have suspicious lymph nodes increased in size, is the patient having oral pain, is the pain changing and finally does the patient feel the lesion is growing rapidly?

Fig. 34.2 Photograph of a patient with PVL. All three photographs are from the same patient. The patient has extensive involvement of the maxillary and mandibular gingival, buccal mucosa and palate. As depicted here PVL is characterized by extensive verrucous-appearing lesions with areas of ulceration.

Fig. 34.3 Histologic progression of PVL. The stages of histologic progression of PVL include (a) hyperkeratosis, (b) verruciform hyperkeratosis, (c) verrucous hyperplasia, (d) verrucous carcinoma, and (e) squamous cell carcinoma.

Most oral cancers are painful.⁵⁶ Pain is the most common presenting symptom for patients with oral cancer. For oral cancer patients, pain severely limits their oral function including eating, drinking, and talking.⁵⁶ Pain is rated as the oral cancer patient's worst symptom and is the primary determinant of a poor quality of life.^{56–59} In their final period of life, pain is reported by 85% of oral cancer patients as their most common problem.⁶⁰ Opioids, such as morphine, are the only drugs that have any efficacy for oral cancer pain. Morphine provides minimal relief, does not restore oral function and progressively larger doses are required; therefore, tolerance rapidly develops. Despite these findings and the severe nature of oral cancer pain, surprisingly little research has been done to understand the etiology of pain associated with oral cancer or to discover effective analgesics. The University of California San Francisco has developed and validated a questionnaire specifically for patients with oral cancer pain.^{56,61} This questionnaire can be used to monitor pain control either during the preoperative phase or during the late stage of disease following treatment failure. Pain management should be tailored to provide relief when patients are required to function. Total resection of the oral cancer produces near complete relief.⁶¹ However, patients have severe pain prior to surgery, some oral cancers are unresectable, some patients are too sick to have surgery, and many patients develop a recurrence of the cancer or a second primary oral cancer. Approximately 50% of oral cancer patients will not be cured with surgery, chemotherapy, or radiation therapy. The surgeon, as the head of the multidisciplinary team, must remind members that oral cancer patients experience excruciating pain during their final months of life.

The tobacco history should be reviewed and the patient should be classified as a never smoker, non-smoker, or smoker. If the patient is a smoker or non-smoker the pack-years of use should be calculated. If the patient is a non-smoker the time since the patient's last cigarette should be determined. While there is conflicting data in the literature as to whether marijuana use contributes to oral carcinogenesis,^{62–64} patients should be asked whether and how much marijuana they use.

Systematic palpation of the neck should be performed on every patient at every visit.⁶⁵ Palpation of the neck should be performed on one side of the neck at a time and should always be performed from behind the patient. The sensitivity of clinical exami-

nation to detect metastasis, even by expert surgeons, has been inadequate, with a sensitivity of 51% reported by one major head and neck surgery group.¹⁰ Other groups have also reported on the low sensitivity of clinical exam, ranging from 60–70%.^{66–68}

A panoramic radiograph should be performed in almost all cases of oral cavity SCCs. Even if the carcinoma does not involve the maxilla or the mandible the dentition should be evaluated prior to surgery to determine whether extractions will be required at the time of surgical resection if postoperative radiation therapy is anticipated. Nasopharyngoscopy can be easily and painlessly performed with proper preparation of the nasopharyngeal membranes with local anesthetic and a topical vasoconstrictor. Nasopharyngoscopy can be used to evaluate the nasopharynx, base of tongue, and supraglottic structures.

The significant limitations of imaging for detecting carcinoma need to be considered when evaluating the oral cancer patient, particularly when attempting to identify metastasis in the oral cancer patient who is N0 on clinical exam. Imaging, in the forms of computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), ultrasound (US), or now PET/CT, has been used to assess primary tumors. Unfortunately, despite improved resolution and software analysis, all imaging techniques are still insufficiently sensitive for detecting occult neck metastases, with 20–45% of patients staged as N0 using these techniques having occult nodal involvement on pathologic evaluation of the neck.^{10,69,70} In order for imaging techniques to be useful in making treatment decisions, they must be able to detect metastatic nodes that are found in patients with early stage tumors, nodes that are present only 20–45% of the time. These nodes are commonly small, with diameters as small as 3–10 mm. Also, the long axis of these nodes, which can be visualized accurately on pathology, is often not parallel to any of the planes used for anatomic imaging which causes even greater foreshortening.^{70,71} The presence of structural changes, such as cystic changes or necrosis, aids in detection, however these features are rarely present in occult disease. In addition, within this group of patients, these techniques must not only be sufficiently sensitive to detect microscopic disease but also specific enough so that frequent false-positive results do not render universal prescription of elective neck treatment.

Anatomic imaging studies such as MRI and CT have been shown to have similar accuracies, with

sensitivities ranging from 56–85% and specificities from 47–95%.^{72–75} PET has a sensitivity of approximately 75–90% and specificity of 90–100%. One must consider that in most of the studies which have attempted to measure sensitivity and specificity the patients did not exclusively have N0 necks. One would expect the sensitivity and specificity to be much lower for detecting occult nodes in earlier stage disease.

Preoperative imaging of the primary cancer and the head and neck should include CT or MRI. MRI is often more helpful than CT in evaluating the primary cancer because of the high soft tissue resolution

Fig. 34.4 Coronal view of MRI of lateral tongue squamous cell carcinoma. MRI can provide high resolution and anatomic detail which aids in clinical staging and surgical planning.

Fig. 34.5 Dental artifact from amalgam obscuring CT. One of the significant drawbacks of CT in the evaluation of an oral cavity primary is the artifact generated by dental materials.

which MRI provides (Fig. 34.4). Moreover, MRI is less obscured by the dental artifact that occurs with high density materials such as dental amalgam. CT can aid in the evaluation of bone involvement; however, its usefulness is often limited by such dental artifact in the area of interest (Fig. 34.5). When reviewing the MRI, all views should be closely examined to help understand the extent of tumor invasion. Depending on the anatomic structure being evaluated, particular views will give more information regarding the extent of invasion. The following recommendations are for interpreting MRI images. Evaluation of oral cavity primary can be difficult and often T1, T2 and gadolinium-enhanced views are required. Fat saturation should be used for postgadolinium and T2 views. The coronal plane is often most helpful for evaluating the primary, particularly the tongue (Fig. 34.4). In evaluating the mandible the T1 images are most helpful to determine if the marrow is involved. T2 and gadolinium-enhanced views, both using fat saturation, provide the most information regarding inferior alveolar nerve involvement (Fig. 34.6). For assessment of mandibular invasion both the axial and coronal planes are critical. Evaluation of cervical nodes is often required in the presurgical setting as well as in the postsurgical setting during follow-up. Cervical nodes are best evaluated with the axial plane views. For presurgical evaluation the T2 view is often the most useful. Following surgery the T1 view can be more helpful due to intensity changes that occur in the nodes following surgery.

PET imaging with fluorine-18 fluorodeoxyglucose (FDG) has been shown to have a higher sensitivity and specificity than traditional CT or MRI in the evaluation of the patient with head and neck SCC.⁷² However, the results of PET scan rarely change the treatment decision in the management of oral SCC. In the case of an N0 neck in a patient with oral SCC the ¹⁸F-FDG PET scan does not have a clear role.^{76,77} The poor resolution of PET/CT makes it difficult to use for surgical planning. Nahmias *et al.* examined the staging capacity of PET/CT on a node by node

Fig. 34.6 Perineural invasion in a 35-year-old woman with oral SCC of the gingivobuccal sulcus. The patient complained of a numb chin. Axial T1 MRI weighted image (left) shows subtle soft tissue thickening (arrow) in right gingivobuccal sulcus adjacent to the right mental foramen. Adjacent T1 weighted image (center) shows marked thickening of the right inferior alveolar nerve within the mandible (arrows), suspicious for perineural carcinoma involvement. Coronal T1 weighted image (right) with fat saturation shows an asymmetrically thickened and more enhancing right inferior alveolar nerve (arrow) compared to the normal left side (open arrow). Pathologic evaluation of the resected specimen demonstrated carcinoma involving the mental nerve first 3.5 cm from mental foramen at surgery.

basis.⁷⁷ In this carefully performed study, the investigators mapped out each node from a neck dissection and then compared it to the corresponding node that was visualized on the preoperative PET/CT. Their study included a total of 70 patients with oral cancer, 47 of which had N0 necks and 19 of which were clinically N+. In their 47 N0 patients, they found that the sensitivity and specificity of PET/CT for detecting patients that have metastatic nodal involvement was 79% and 82% respectively, with a positive predictive value (PPV) of 68% and a negative predictive value (NPV) of 89%. When analyzing on a node by node basis in N0 patients, the sensitivity and specificity was 26% and 99% respectively, with a PPV of 63% and a NPV of 95%. Nahmias *et al.* concluded that, due to a NPV of 89% and a false-negative rate of 11%, the use of PET/CT was not helpful in ruling out occult nodal metastasis to a degree that would affect a surgeon's decision to electively treat the neck.

In a prospective study of 31 oral cancer patients with N0 necks it was found that the role of ¹⁸F-FDG PET is limited due to the combination of limited sensitivity for small metastatic deposits and a relatively high number of false-positive findings.⁷¹ Schoder *et al.* found, in a cohort of patients with N0 necks, that PET/CT had a sensitivity and specificity of 67% and 85% respectively.⁷¹ They determined, using histopathology, that nodes 3mm or smaller could not reliably be detected by PET/CT. Thus Schoder *et al.* concluded that, despite overall high accuracy, PET/CT has limited clinical utility in this application due to the inadequate sensitivity for small nodes and a high number of false-positives (13%). They also emphasize in their paper that the surgeons in their group had the results of the PET/CT before treatment planning, and that in none of the patients did the information alter the decision to operate.

PET has been proposed to evaluate for distant metastasis but distant metastasis is rare in oral SCC. PET scans are also associated with a false-positive rate which often obligates the clinician to pursue "hot spots" often leading to a delay in treatment. PET scans theoretically could impact on the decision to perform a neck dissection; however, micrometastasis is unlikely to produce a positive PET result. The rate of occult metastasis for almost all oral cavity SCCs dictates that a neck dissection should be performed regardless of the results of a CT, MRI, or PET scan. With the currently available technology a PET scan often gives false security or false worry in the initial assessment of patients with oral cavity SCC. Moreover, indiscriminant use of the PET scan significantly burdens the health care system. The PET scan can be helpful in evaluating oral cancer patients with symptoms suggestive of recurrence when no clinically apparent lesion is found; it also clearly has a role in the patient with an occult primary head and neck cancer.

The neck can also be evaluated with ultrasound. Van den Brekel and Castelijns' group has reported in

multiple studies their success with using ultrasound-guided fine-needle aspiration biopsy with a "wait and see" approach for patients with N0 necks.^{66,78-81} In one such study, Nieuwenhuis *et al.* reported that 21% of their patients using this strategy developed nodal disease during follow-up. These patients were then treated with a therapeutic neck dissection of levels I-V, with a salvage rate of 79% at 5 years.⁷⁸ However, it appears that diagnosing occult metastasis with ultrasound is highly technique-sensitive and user specific, as other studies have not been able to replicate these authors' success.^{10,82}

A chest radiograph is part of the standard work-up recommended by the National Comprehensive Cancer Center Network for head and neck cancer patients. The role of the chest radiograph is for the evaluation of distant metastasis. Approximately 1% of patients with a head and neck SCC will have a synchronous primary in the lung.^{83,84} For patients with oral cavity SCC a chest CT would only be indicated in the setting of advanced cervical involvement or if a suspicious lesion were identified on the chest radiograph.⁸⁵ The use of panendoscopy is dependent on the provider and concern regarding a second primary. The cost effectiveness of panendoscopy is questionable given the relatively low incidence of second primaries.

Following the history and physical examination each patient should be staged according to the AJCC staging system.²⁵ Clinical tumor staging should be based on all clinical, imaging, and pathologic data.²⁵ The surgeon must complete a staging form for each patient and submit this form to the medical center's cancer data management office. Every oral cancer patient deserves to be presented at a multidisciplinary tumor board. Management of oral cavity SCC almost always involves surgical resection with consideration of adjunctive chemotherapy and radiation therapy. Because of the significant, progressive side-effects, radiation therapy should be avoided if possible, as will be discussed below.

In planning for surgery patient performance should be evaluated. The Karnofsky index will give a good estimate of the patient's ability to tolerate surgery, radiotherapy, and chemotherapy.⁸⁶ The patient's goals for treatment should be discussed and considered. The wishes of the patient and family must be weighed heavily when considering treatment options. The question is often raised of what to do with an elderly patient with a limited life expectancy. It is often a mistake to not treat the cancer since many of these patients will live much longer than expected and if the cancer is not treated patients will progress to endure profound pain. Surgical resection offers significant pain relief.⁶¹

Nutritional support has many benefits for the surgical patient, including improved healing following surgery, decreased complications, lean body mass preservation, and improved quality of life. A common belief among clinical oncologists is that the

above mentioned benefits of nutritional support have an inverse negative impact on the malignancy. The surgical oncologist might be surprised that such nutritional support is potentially benefiting the head and neck carcinoma as well. A secondary analysis of Radiation Therapy Oncology Group (RTOG) 90-03, a prospective randomized trial evaluating four definitive radiation therapy fractionation schedules in patients with locally advanced head and neck SCC, prospectively collected data on the nutritional status of the 1073 evaluable patients. Nutritional status of the patients was analyzed against therapy toxicity and outcome.⁸⁷ This analysis is the largest evaluation of prospectively collected nutritional support data and the impact of nutritional support on treatment outcome in patients with cancer participating in a clinical cooperative group trial. Contrary to the result anticipated, nutritional support prior to therapy was shown to be a highly significant independent prognostic factor for increased locoregional failure and death. The reason for this result can possibly be found in a large prospective trial analyzing 92 patients with gastrointestinal cancer and malnutrition. The study evaluated the impact of nutritional support and found that parenteral nutritional support lead to a significant increase in tumor proliferation as measured by cells in S phase, DNA content, and DNA index.⁸⁸ Clearly, the role of nutritional support in the management of the oral cancer patient is potentially controversial and the surgical oncologist must weigh the benefit of nutritional support against the potential negative impact on cancer control.

Meticulous planning prior to surgery will tip the balance in favor of a favorable patient outcome. All studies should be carefully reviewed. Surgical planning should include plans for airway management, discontinuation of coagulants, and necessary preoperative planning with bridging therapy, planned ablation, and reconstruction. Tracheostomy is rarely required in the setting of an oral resection with a neck dissection.⁸⁹ Nasotracheal intubation is generally a safe alternative to tracheostomy. Tracheostomy is strongly favored if a microvascular free flap is planned or if there are concerns for postoperative edema. If the patient requires a return to the operating room for salvage of a dying flap, intubation in the setting of a newly constructed oral cavity and oropharynx can be difficult.

Surgical treatment of oral cancer based on subsite

Nothing impacts on patient outcome more than the oncologic surgeon's attention to detail at the time of primary resection and dissection of the neck lymphatics. Because the structures that are affected by oral cancer impact directly on oral function, for example chewing, a comprehensive understanding of the functional aspects of the anatomy, such as

occlusion, is required to provide the patient with restoration of function. An appropriate margin of normal mucosa must be resected with the primary. The surgeon's focus at the time of surgical resection must be on maintaining such an appropriate margin around the carcinoma and avoiding violation of the carcinoma. The clinical implications of an appropriate cuff of histopathologically normal tissue around a resected cancer have been extensively studied and reported.⁹⁰⁻⁹⁷ The distinctions between clear, close, and involved margins have been variable throughout the literature and arbitrary in designation;^{97,98} however, it is generally agreed that proximity of the cancer to the resection margin is a strong negative prognostic finding. Given the anatomic complexity of the oral cavity, achieving an adequate margin following resection of a cancer is difficult and frequently the histopathologic margins are reported to be significantly short of those measured clinically, the *in situ* margin. The discrepancy between the pathologic margin and the *in situ* margin might explain the high rates of close or positive margins reported in the recent literature.^{38,97,99,100}

To achieve an appropriate margin at the time of surgery, the extent of the primary should be determined based on a review of available imaging prior to surgery and on visual inspection and digital palpation once the patient is under general anesthesia. The primary can then be marked out with a surgical marking pen followed by careful measurement of a 1–1.5 cm margin (Fig. 34.7). The 1 cm margin is arbitrary and there has been no study to demonstrate that this critical cutoff of 1 cm measured around the primary *in situ* shows improved tumor control. It is tempting to suggest that increasing margins of resection universally should be adopted, in light of the increased availability of improved reconstructive options with microvascular free tissue transfer. However, increasing margins of resection from 1 cm to a higher standard has not yet been shown to improve prognosis. While the surface margins guide the initial incision, three-dimensional conceptualization of the cancer is critical as the resection is carried deeper. A 5 mm margin of histopathologically normal mucosa is the accepted designation between clear and close in terms of differences in prognosis.^{90,98} Finger extensions or islands of tumor may invade out of the main mass of tumor resulting in a margin that is closer than anticipated.³⁸ Alternatively, tissue retraction that occurs following resection and pathologic processing of the specimen may cause the margin of tissue to decrease in size.¹⁰⁰ Molecular biologic techniques have shown that even when margins are judged "clear" on histopathologic review, genetic changes often remain in normal-appearing mucosa, changes that increase the risk of local recurrence.¹⁰¹⁻¹⁰³ This potentially wider and invisible area of genetically altered cells with premalignant genetic aberrations makes blindly aggressive resection ineffective. The appropriateness of the final surgical margin var-

ies with the oral subsite resected.¹⁰⁰ As the adequacy of resection margins is paramount to successful treatment, it would be prudent to consider varying the size of the margin of resection based on tumor location, stage, or any other clinical factor that may affect margin status unfavorably. While the discussion below is based on oral cavity subsite, in many cases of oral SCC contiguous structures are involved. In such cases in continuity resection of the involved structures, with the neck dissection if possible, should be performed (Fig. 34.8).

Tongue

The tongue is the most common oral site for SCC. Tongue carcinoma infiltrates the parallel muscle fibers and there is no fascia to resist invasion. The rich lymphatic supply leads to early cervical metastasis. The lymphatic drainage of the lateral tongue, the most common portion of the tongue affected, is into the submandibular and jugulodigastric nodes. The base of tongue is embryologically, anatomically, and biologically distinct from the oral tongue. Base of tongue SCC responds well to chemotherapy and radiation. In clear distinction, surgery, with consideration of postoperative chemoradiotherapy, is the primary treatment for oral tongue SCC. If possible the tongue should be resected with continuity with the neck. However, this approach requires a flap, either microvascular or local, to prevent communication between the oral cavity and the neck. If the primary and neck are resected separately then the intervening lymphatics, within the floor of mouth along the mandible, are at risk for metastasis following surgery. The intervening lymphatics in the floor of mouth and submandibular region are a rare but reported site of failure in patients undergoing partial glossectomy and neck dissection. The tongue anatomy must be carefully considered when resecting the tongue. A common error is to measure and follow a 1 cm margin

on the surface but to not achieve a 1 cm margin in the deep aspect of the tongue. Even for superficial SCCs of the tongue a 1 cm deep margin will almost take the surgeon to the tongue midline. The depth should be established at the lateral margins of the tongue resection prior to carrying the dissection to the deep portion (Fig. 34.7).

Commonly used methods of tongue reconstruction include a split-thickness skin graft or a microvascular free flap. The microvascular free flap adds bulk and can restore articulation. The decision regarding reconstruction must be based on the patient's expectations, requirement for function, planned resection, and health status. For patients who have had a near-total or total glossectomy the need for microvascular reconstruction is clear. However, for resections comprising the hemitongue or less, the remaining tongue compensates significantly. Speech intelligibility scores with tumors in the anterior are significantly lower than those in the middle or posterior tongue. When the tip of the tongue or floor of the mouth can be preserved, intelligibility scores increase. The more anterior portions of the tongue participate in the articulation of consonants including plosive, fricative, affricate, and nasal.^{104,105} These sounds require

Fig. 34.7 Intraoperative measurement of resection margins for oral SCC. At the time of surgical resection great care should be taken to establish the appropriate margin in three dimensions. The lesion should be carefully marked out based on review of the appropriate imaging studies, as well as visualization and palpation of the lesion. The surface surgical margin should be marked out (left). The imaging studies can be used to predict the depth of infiltration. Once the resection is started the appropriate depth, based on estimated depth of infiltration and appropriate surgical margin, should be carefully established and measured prior to dissecting deep to the carcinoma (right).

Fig. 34.8 The resected and labeled specimen from a 58-year-old man with an SCC involving the mandibular and maxillary gingiva, oropharynx, and the buccal mucosa. The specimen has been resected in continuity with the ipsilateral neck lymphatics. When possible the entire primary should be resected in continuity with the neck dissection. A dissection that is not performed in continuity places the intervening lymphatics between the primary and cervical lymphatics at risk.

the cooperation of the tongue with surrounding structures such as the palate, teeth, and alveoli. There are very few comparative studies in English on articulation intelligibility in patients that do or do not have microvascular reconstruction. A comparison of the radial forearm free flap with the adjacent tongue dorsal flap demonstrated that for patients having a resection within the range of a hemitongue there was no difference between the two groups.¹⁰⁶ Patients with preservation of the tip or floor of the mouth had higher intelligibility. However, all patients in this study spoke Mandarin Chinese. Urken has shown that excellent sensory function can be maintained when a neural anastomosis with a radial forearm flap is performed; however, this is not commonly performed during microvascular flap reconstruction of the tongue.¹⁰⁷

A comprehensive discussion of management of the neck is presented later in the chapter. Because of the high incidence of oral tongue SCCs, the management of the neck for early tongue SCC will be briefly discussed here. The question as to how to handle the neck in patients with early stage (T1–T2) tongue SCC in the setting of no neck involvement has been addressed in all regions of the world and it is clear that elective surgical management of the neck should be performed.^{108,109} Patients should be treated with an ipsilateral neck dissection at the time of tongue resection. Such an approach leads to improved patient outcome and survival. A review of 380 patients with early stage (T1–T2N0) tongue SCCs demonstrated that patients treated with elective neck dissection have improved neck control rates and overall survival compared to patients that were simply observed.¹¹⁰ Primary radiotherapy has no role in the management of tongue cancer due to poor tumor control rates and the incidence of short- and long-term complications secondary to radiation therapy.¹¹¹

Maxillary gingiva

Presenting an evidence-based approach to the management of patients with maxillary gingival SCC is difficult given that few studies have documented associated metastatic rates and patient outcomes. In particular, there is limited information with regard to occult skip metastasis to the neck, bypassing the parapharyngeal and superficial buccal lymphatic systems.^{112,113} Maxillary gingival oral SCCs are rare compared to other oral cancer sites.¹¹⁴ SCC of this oral site poses complex management issues in terms of resection, reconstruction, and consideration for postoperative radiotherapy.

At initial presentation maxillary palatal, gingival, and alveolar squamous cell carcinomas manifest clinically detectable cervical metastasis at rates in the range 11.5–28.5%.^{115–118} The occult cervical metastatic rate ranges from 15.8–38.0%.^{115–118} Such metastatic rates are comparable to tongue, floor of mouth, and mandibular gingival squamous carcinomas where

the likelihood of occult neck disease reaches 30%.^{108,119–121} Montes and Schmidt have found an occult metastasis rate in patients with maxillary SCC to be 21.4%.¹¹⁸ Ultimately 50% of this patient group will develop regional or distant metastasis.¹¹⁸ The average time to regional failure in the clinically negative neck in patients with maxillary gingival SCC is 9.75 ± 6.37 months.¹¹⁸ Simental *et al.* report regional failures occurring an average of 10.4 months following surgery.¹¹⁶ When the few available studies addressing cervical failure in patients with maxillary SCCs are considered, the failure rate is as high as 50%.^{116–118}

In addition to proper management of cervical lymphatics, ablative accuracy is required for success in treating maxillary SCCs. Compared to all oral sites, maxillary alveolar carcinoma can be one of the most difficult areas to completely resect with proper margins.^{38,100} Maxillary alveolar specimens exhibit a high incidence of positive margins.³⁸ Woolgar *et al.* have proposed that the difficulty in obtaining oncologically proper margins is attributed to: (1) tumor spread along the vestibule; (2) unrecognized infiltration into the submucosal plane and buccinator muscle; and (3) surgeon's desire to limit the morbidity of resection.³⁸ Simental *et al.* have demonstrated a local failure rate of 29.2%.¹¹⁶ The area of greatest concern in terms of infiltration is the pterygoid fossa. Posterior access can be significantly improved with the Weber Fergusson approach. For large maxillary SCCs a combination of the Weber Fergusson and Trotter (subciliary) approaches can be used to increase access and allow for total removal (Fig. 34.9).

Local and regional failure both contribute to poor patient outcome. Patients with maxillary palatal, gin-

Fig. 34.9 Weber Fergusson approach with Trotter (subciliary) extension for resection of maxillary lesions. The approach can be used to increase access to the posterior pterygomaxillary region. The Trotter extension should only be used if it affords additional and necessary access. Most maxillary lesions can be removed with a transoral or Weber Fergusson approach alone.

gival, and alveolar carcinoma have an overall 5-year survival rate of 59–69%.^{115–117} Salvage success for regional failure of other oral site cancers has been reported to be between 29 and 60%.¹²² For maxillary SCCs the 34.6% regional failure rate is successfully managed in 66% of cases.¹¹⁶ There are no outcome data relative to salvage surgery for local recurrence of maxillary palatal, gingival, and alveolar squamous carcinomas. As with other oral sites, early local recurrence is a poor prognostic indicator.¹²²

Reconstruction of the maxillary defect following tumor resection continues to pose a challenge for the reconstructive oral and maxillofacial surgeon. Currently available maxillary reconstructive techniques include placement of a prosthetic obturator, local and regional flaps, and microvascular free flaps, each with specific indications and advantages depending on the ablative defect, the medical status of the patient, and the patient's prognosis.^{123–126} The meticulously fabricated maxillary obturator has a long history of effectively managing the functional, cosmetic, and psychological problems associated with a maxillectomy defect. However, the lack of retention, support, and stability are significant problems following extensive ablation of retentive maxillary anatomy. In a patient who is reconstructed with a maxillary obturator, a split-thickness skin graft, as well as removal of the inferior turbinate, should be performed in every case (Fig. 34.10). The split-thickness skin graft will aid with obturator insertion and removal, and resection of the inferior turbinate will significantly improve obturator retention.

Fig. 34.10 Maxillectomy defect reconstructed with a split-thickness skin graft. If the planned reconstruction of a maxillectomy defect involves a maxillary obturator then a split-thickness skin graft should always be placed. The skin graft will aid in the comfort of obturator insertion and removal. The inferior turbinate should also be removed to prevent displacement of the obturator.

There are few reconstructive options for patients with near total or total maxillectomy defects. Schmidt *et al.* have described the use of zygoma (zygomaticus) implants for retention of the maxillary defect in these patients.^{127,128} Zygoma implants were originally designed for reconstruction of the atrophic, edentulous maxilla;¹²⁹ however, the combination of zygoma and standard endosseous implants can be used to retain and support a maxillary obturator following extensive resection of the maxilla. Twenty-one percent of zygoma and 30% of standard endosseous implants fail in patients with extensive maxillary resections.^{127,128} A higher failure rate than is traditionally encountered should be expected, most likely due to radiation therapy that is often required in this patient group. Radiation has a clearly negative impact on the reparative capacity of bone.¹³⁰ The success rate for standard endosseous implants is lower in the irradiated oral and maxillofacial region.¹³¹ Parel *et al.* reported a success rate of only 61.1% for craniofacial implants placed in irradiated bone.¹³² The use of hyperbaric oxygen therapy in patients having implant reconstruction following radiation therapy is controversial.¹³³

The biomechanical forces placed on zygoma and standard implants following an extensive maxillectomy are significantly greater than the forces observed in a conventional implant reconstructive case. The quality and quantity of remaining bone available for osseointegration following an extensive maxillectomy are compromised. The lever arm placed on zygoma implants is significantly greater than the lever arm placed on standard endosseous implants. Resection of all palatal and alveolar bone might be required in a patient requiring a maxillectomy. In this case, the only bone available for integration of the zygoma implant is the zygomatic bone at the junction of the temporal and frontal process. Therefore, zygoma implants are at a 30–60° angle relative to the occlusal force and only have one site distal to the occlusal force available for integration. Because of these biomechanical requirements such cases should be over-engineered and as many zygoma and standard implants should be placed as possible (Fig. 34.11).

Zygoma implants should be placed at the time of resection given that most patients will require radiation therapy within 2–3 weeks of maxillary resection. Zygoma implants are significantly more difficult to place if not placed at the time of resection. Placement of zygoma implants at the time of resection requires meticulous planning by the maxillofacial prosthodontist and surgeon. Despite these problems patients reconstructed with this method have highly favorable speech and esthetics and are able to drink and eat without nasal leakage.

Microvascular free flap reconstruction can be used for patients requiring a maxillectomy. There are few studies available which have evaluated quality of life following maxillary reconstruction. There is a single quality-of-life study which evaluated the outcome of

Fig. 34.11 Reconstruction of a patient requiring near-total maxillectomy for SCC, utilizing bilateral double zygoma implants. There was no remaining bone for standard endosseous implants. Postoperative lateral cephalogram (left). An attempt was made to separate the four zygoma implants as much as possible in three planes of space. Postoperative posteroanterior cephalogram (right). The zygoma implants were placed to capture the maximum amount of bone at the junction of the temporal and frontal processes of the zygoma.

maxillary reconstruction with a maxillary prosthetic obturator.¹²⁴ Rogers *et al.* evaluated quality of life in patients requiring maxillectomy for oncologic reasons who were reconstructed with either a microvascular free flap or a maxillary obturator without implants.¹³⁴ The authors used eight quality-of-life questionnaires, including the Denture Satisfaction¹³⁵ and Obturator Functioning Scale.¹²⁴ There was no difference in quality of life between the patients reconstructed with a microvascular free flap to those reconstructed with a prosthetic obturator. A critical point of this study is that only eight of 18 patients reconstructed with a free flap were able to wear a conventional denture.¹³⁴

Mandibular gingiva

Similar to maxillary gingival SCCs, there are few dedicated studies that have looked at the biologic behavior of the mandibular gingival SCC.¹³⁶ Management of the mandibular SCC almost always requires resection of the mandible and reconstruction. Mandibular reconstruction has been discussed in detail in another chapter in this volume and will not be discussed here.

One of the most difficult aspects of managing mandibular gingival SCC is determining the degree of mandibular invasion, as well as the extent and method of mandibular resection.¹³⁷ For oral cavity SCC with the potential for mandibular involvement determination of the amount of bone involvement and how much mandible should be resected are critical for surgical planning and will directly impact on patient outcome. CT is often used as the study of choice for determining the degree of bone involvement; however, dental artifact can prohibit accurate interpretation of the critical CT views. Oral SCC on MRI has an intermediate signal on T1 weighted

images and appears similar to muscle. MRI views of the mandible can be difficult to interpret due to changes secondary to periodontal disease and other inflammatory changes. MRI can be helpful in assessing marrow involvement as well as possible perineural invasion. One problem with MRI is the potential to overpredict mandibular involvement, leading to resection of more mandible than is required for oncologic principles. A prospective study designed to determine the accuracy of available studies for predicting mandibular invasion showed that bone scintigraphy and MRI overpredict and CT and panoramic radiograph underpredict mandibular invasion.¹³⁸ Panoramic radiograph, MRI, and bone scintigraphy are associated with a high false-negative rate when used to predict mandibular invasion.¹³⁹ Periosteal stripping with direct inspection of the mandible has been proposed to determine both the presence and extent of tumor invasion of the mandible.¹³⁸ Brown recommends using clinical examination, periosteal stripping, and at least two imaging techniques that have complementary specificity and sensitivity when deciding to resect the mandible.¹⁴⁰ Cone-beam CT can be used in certain circumstances to help guide the resection margins.¹⁴¹ While standard oncologic principles should be followed the clinical findings and available studies should be carefully reviewed and surgical treatment tailored to the specific patient and the mandibular lesion.

For most mandibular gingival SCCs segmental resection with a 1 cm margin is the recommended approach. A marginal mandibulotomy can be used to resect a gingival SCC in very select cases;¹⁴² however, technical vigilance is required to not create a thin mandible which can easily fracture under the opposing forces of the pterygomasseteric sling and the suprahyoid muscle. It is often difficult to get an appropriate 1 cm margin and avoid thinning the mandible to the point of pathologic fracture (Fig. 34.12). Marginal mandibulectomies also make it difficult to perform an in-contiguity resection with the neck dissection placing the intervening lymphatics at risk for harboring occult metastasis. Reconstruction of a marginal mandibulectomy defect with a bone graft and ultimately endosseous dental implants is extremely prohibitive. The planned osteotomy should take into consideration the classic, and sometimes conflicting, work of McGregor, MacDonald, and Brown.^{143–147} Gingival SCC can invade the alveolar bone at the site of gingival attachment to the teeth and/or at the point of abutment of the carcinoma to the mandible. The mandibular osteotomy must be below the apices of the teeth.

Buccal mucosa

The buccal mucosa lines the oral cavity from the maxillary to the mandibular attached gingiva and progresses posteriorly to the pterygomandibular raphe. The buccal mucosa drains to the submental, subman-

Fig. 34.12 Pathologic fracture in a patient following marginal mandibular resection for a mandibular gingival SCC. Preoperative panoramic radiograph (top) with the area of carcinoma pointed out (white arrow). A marginal mandibulectomy was planned. When a marginal mandibulectomy is planned the resection must be below the apices of the involved teeth. The postoperative panoramic radiograph shows the resection with the appropriate margin (middle). The inferior border is intact but thin. Two weeks following the operation the patient suffered a fracture (bottom). The patient required open reduction and rigid internal fixation.

dibular, and periparotid lymph nodes. Oral SCCs involving the buccal mucosa are typically aggressive in growth and invasion and this invasive pattern is reflected in the poor prognosis of patients with buccal mucosal SCC. The biologic behavior of these SCCs is reflective of the anatomy of the region which is rich in lymphatics and blood supply. The buccal space contains Stensen's duct, buccal fat, facial artery, and facial vein. Buccal mucosal SCCs are prone to buccal fat and muscle invasion, as well as Stensen's duct involvement. There is not an anatomic boundary to prevent spread of carcinoma. Local recurrence rates are very high, ranging from 45–100%.^{148–150} Locoregional failure leads to poor survival.¹⁴⁸ Sieckza

et al. demonstrated that, even for low T-stage carcinomas, negative margins are not adequate predictors of local recurrence which was 56% in this study.¹⁴⁹ Patients with close or positive margins had a 66% local failure rate as compared with 52% when surgical margins were negative (≥ 5 mm following tissue fixation).¹⁴⁹ Patients who had T1 or T2 SCCs had a 40% local failure rate with surgical resection alone. The available studies favor the use of postoperative radiotherapy to improve local control. As discussed in this chapter postoperative radiotherapy is reserved for oral SCC patients that have close (≤ 5 mm following tissue fixation) or positive margins or have evidence of cervical metastasis. There is also a high

tendency towards regional failure.^{148,149} Evaluation of the degree of infiltration can be extremely difficult in patients with buccal mucosal SCCs. CT or MRI is often not helpful given that the buccal mucosa collapses against the alveolus. One method to improve interpretation of the selected scan is to place gauze between the buccal mucosa and alveolus to separate the two structures and allow for evaluation (Fig. 34.13).

Reconstructive options for buccal mucosal SCCs will depend on the size of the defect. The alternatives include a split-thickness skin graft, local flaps including the nasolabial flap and buccal fat, and microvascular reconstruction. For posterior buccal mucosal SCCs in the region of the pterygomandibular raphe, patients will often experience postoperative trismus which is particularly pronounced when radiation therapy is given. Patients should be encouraged to begin jaw-opening exercises as soon as possible following surgery. They should be advised to continue through radiation therapy. Patients will often experience pain with the jaw-opening exercises and analgesics should be taken before the exercises.

Floor of the mouth

Squamous cell carcinoma of the floor of the mouth is associated with a high rate of local recurrence¹⁵¹ and high rates of cervical metastasis, even when the primary is small.¹⁵² Similar to other oral cavity SCC primaries a neck dissection is indicated. Unless the lesion is truly a lateral lesion then a bilateral neck dissection is indicated. Involvement of the sublingual gland is common. Obtaining a 1 cm margin on the deep margin can be difficult without resecting the primary in continuity with the neck dissection. A mandibulotomy significantly improves access and allows for resection of the specimen in continuity with the neck (Fig. 34.14). A parasagittal mandibulotomy can be used to resect floor of mouth, lateral tongue, base of tongue, maxillary, parapharyngeal, and skull base tumors.¹⁵³ If attention is given to strict control of the occlusion, which can be aided by the use of a lingual splint, morbidity associated with the mandibulotomy is minimized.¹⁵³

Fig. 34.13 Imaging technique to improve visualization of buccal mucosal lesions. A biopsy-proven buccal mucosal SCC is pictured on the left. CT or MRI imaging of these lesions can be difficult because when the patient closes the buccal mucosa collapses against the teeth and alveolus. Gauze can be placed between the buccal mucosa and teeth during the scan (right) which improves visualization of the lesion (arrow).

Reconstruction of the floor of mouth defect following resection should be based on the following: size of the defect, whether the defect communicates with the neck, planned postoperative radiation therapy, and health of the patient. If there is communication between the oral cavity and neck, the patient's health will tolerate a prolonged general anesthetic, and postoperative radiation therapy is planned, then a microvascular free flap is likely the treatment of choice. Smaller defects where the mylohyoid muscle is maintained can be reconstructed with a split-thickness skin graft and temporary bolster. The inferiorly based nasolabial flap is an excellent alternative to the microvascular free flap. Rose initially described the use of the one-stage arterialized nasolabial island flap for floor of mouth reconstruction.¹⁵⁴ The skin portion of the flap is centered on the nasolabial fold and extends from the medial canthal area to 2 cm superior to the mandibular margin. The nasolabial flap can be harvested to contain the subcutaneous tissue and facial muscles with the associated vessels. Harvesting of the associated vessels made the flap considerably more reliable than the subcutaneous flap. Harvesting of the underlying muscles added to the mobility of the flap. Hagan and Walker formally described the nasolabial musculocutaneous flap.¹⁵⁵ These authors reported that in 15 cases with advancements up to 5 cm there were no cases of necrosis. Bilateral nasolabial flaps can be harvested to cover large floor of mouth defects measuring up to approximately 5 cm in anteroposterior dimension.¹⁵⁶ The advantages of the nasolabial flap for reconstruction of floor of mouth defects include the large amount of tissue the flaps provide and the cosmetic result following closure of the donor site. Potential disadvantages include hair growth from the flap in patients who will not receive radiation therapy and the fact that the flap pedicle must cross over the occlusal table of dentate patients. The flaps should be raised superficial to the facial muscles as two triangular flaps. The flaps can then be tunneled through the cheek and sutured one in front of the other in the floor of the mouth. The flaps are sutured to each other and the margin of the defect. The donor site is closed except for a small area at the base to prevent stricture of the pedicle. The pedicle can be divided and the base closed 2–3 weeks later. With healing of the flaps, the floor of mouth is

Fig. 34.14 A mandibulotomy can improve access for resection. The mandibulotomy provides surgical access to maxillary (left), tongue, base of tongue, and floor of mouth (right, arrow) SCCs.

flat enough to allow placement of a denture. Ioannides *et al.* reported on the use of nasolabial flaps for reconstruction of the floor of mouth in 16 cases; complications were observed in four cases. The complications included scarring, flap dehiscence in two cases, and a bulky flap, preventing placement of a denture.¹⁵⁶

Lip

Lower lip SCC has similar outcome with surgical resection and radiation therapy. Radiation therapy can be particularly helpful with extensive carcinomas that would require resection of the entire lower lip. However, consideration must be given for mandibular involvement which would prohibit the use of radiation therapy. Moreover, radiation therapy will leave the patient with the life-long effects of radiation therapy. Lower lip SCC can be treated with electrons to treat to very high doses and a superficial depth. Lower lip SCCs are generally ultraviolet light induced. If surgery is chosen as the treatment resection margins should be 1 cm. The primary function of the lower lip function is control of saliva and prevention of sialorrhea. The lower lip also functions for articulation. If possible symmetric coverage of the teeth should be maintained. Restoration of cosmesis and function is best achieved with the use of local flaps.¹⁵⁷ The reconstructive plan must include the skin, lip, and buccal mucosa. Many methods are available to reconstruct the lips following resection. The Bernard flap, which can utilize the buccal mucosa for replacement of the wet portion of the lower lip, is an excellent method to reconstruct large defects of the lower lip (Figs 34.15 and 34.16). For extensive resections a microvascular free flap will be required; however, the final cosmetic result is often compromised.

Management of the neck

In this section an evidence-based approach will be described for managing the neck in patients with oral cavity SCC. A description of the surgical details of neck dissection is not within the scope of this chapter. Detailed, surgeon-oriented texts and articles are available that provide a detailed description of the operative technique for neck dissection.¹⁵⁸ An excellent text describing avoidance and management of complications following neck dissection can be found in Gavilán *et al.*¹⁵⁹ Surgery is the treatment of choice for almost every oral cavity SCC. The data overwhelmingly support elective neck dissection for even small T1 lesions given the high rate of occult metastasis with oral cavity SCCs. The goals of treating the N0 neck are twofold: (1) to therapeutically remove the lymph nodes that might harbor carcinoma; and (2) to histopathologically review the surgically resected neck specimen leading to accurate staging which would potentially warrant adjuvant treatment leading to improved cancer control. The “wait and see” practice is the opposing approach to the elective neck dissection and refers to the practice of closely following patients who are N0 at the time of surgery rather than performing a neck dissection. With this approach once a patient fails in the neck a salvage of the patient is attempted. “Wait and see” approaches for the N0 neck have been associated with high failure rates. Salvage rates for the failed neck in patients with oral SCC are extremely poor as will be discussed below.

Managing the N0 neck

Almost all patients who die from oral cancer will fail because of uncontrolled local recurrence or failure in

Fig. 34.15 Drawing showing Bernard flap reconstruction of a lower lip following resection of a lower lip SCC. Modified from Closmann *et al.* *J Oral Maxillofac Surg* 2006; 64: 367–74.¹⁵⁷

Fig. 34.16 Resection of lower lip using a Bernard flap. (a) SCC of the right lower lip requiring resection of approximately 60% of the lower lip to achieve a 1 cm margin. (b) The planned reconstruction is a unilateral Bernard advancement flap. The area to be resected is drawn in red. Burow's triangles are marked in black. The green line represents the area of buccal mucosa to be used to reconstruct the wet portion of the lower lip. (c) Full-thickness resection of the lesion with 1 cm margins is performed. Burow's triangles of soft tissue are removed, incising through skin, subcutaneous tissue, fat and muscle leaving the mucosa intact. Care is taken to place the medial vertical incision of the upper triangle in the nasolabial fold, and the lower medial vertical incision in the melolabial fold. The base of each triangle is approximately one half the length of the defect. A horizontal incision is then placed lateral to the commissure also one half the length of the defect. This incision is to the level of the mucosa. The mucosa is then incised intraorally 1 cm superior to the horizontal incision to create a mucosal flap for lip mucosal reconstruction. (d) Bernard flap sutured in place in tension-free manner.

the neck. Indeed, regional metastasis reduces the 5-year survival rate by half.^{28,160,161} The treatment of the clinically positive neck is straightforward and the purpose is to extirpate the cervical fibroadipose and lymphatic tissues and remove associated structures.^{162–166} Management of the neck when metastasis is not clinically evident (N0) is less clear, given the unpredictable propensity of oral SCC for occult neck metastasis and the associated grave prognosis.^{10,122,167} The decision regarding the N0 neck has been debated extensively.^{168–170} Occult metastatic rates for oral SCC are very high and range from 20–45% for T1 tongue SCCs (Table 34.1).^{10,69,121,171–174} It is clear that when neck metastasis is detected after initial surgery, surgical salvage rates are poor.^{122,175} The downside of performing an elective neck dissection is that it might subject the patient to an unnecessary major surgery and its associated risks, particularly shoulder syndrome.^{94,160,168,169,176} For oral cavity SCC a selective neck dissection (SND) generally refers to the removal of levels I, II, and III with preservation of the sternocleidomastoid muscle, the internal jugular vein and the spinal accessory nerve. A modified radical neck dissection refers to the removal of one of the key structures preserved with the SND and inclusion of level IV.

An elective neck dissection (i.e. performing a neck dissection when there is no clinical or radiographic

evidence of neck metastasis) is often recommended if the chance for occult metastasis is greater than 20%. This threshold is based on the commonly cited study by Weiss *et al.* which proposes that a 20% risk of occult metastasis should be the threshold for treatment of the neck.¹⁷⁷ An intimate understanding of this landmark study is essential when discussing the management of the N0 neck. In this study, Weiss *et al.* performed a computer-assisted mathematical analysis of the decisions and associated outcomes involved with management of the N0 neck, weighing the outcomes with their likelihood of occurrence and relative cost and benefit to the patient.¹⁷⁷ The authors created a decision tree that begins with the decision to operate, to irradiate, or to closely observe with the associated possible outcomes and subsequent necessary decisions. The most distal branches of the decision tree were given probabilities for occurrence based on data from a review of seven clinical series published from 1971–1984.^{166,178–183} Each of the outcomes, including cure, death, cure with surgery, cure with radiation, and cure with salvage, were weighted based on desirability. Desirability was determined by three head and neck surgeons using a “time tradeoff method”. The “time trade off method” refers to how much time of life these surgeons would sacrifice to have better function. Using this methodology, Weiss *et al.* concluded that the benefits outweigh the costs in prophylactically treating the N0 neck when the risk of occult metastasis exceeds 20%. The threshold of 20% has been used extensively in subsequent studies to identify clinical factors, such as stage, tumor thickness, depth of invasion, and histologic characteristics of the invasive front, as the cutoff to make the decision regarding management of the neck. The limitation of the analysis by Weiss *et al.* is that patients’ perception of quality of life is not considered. The work of Weiss *et al.* is an important component in any algorithm that is being used to make the decision on prescribing elective neck dissection. Only one prospective series has attempted to evaluate the clinical utility of the 20% risk for occult metastasis as a

Table 34.1 Studies on occult metastases in T1 tongue SCCs

Author	Date	Site	Occult neck metastases (%)

threshold for elective treatment of the neck.¹⁷¹ O'Brien *et al.* reported on the application of Weiss *et al.*'s decision tree model using clinical criteria, specifically tumor site, tumor stage, and the necessity of accessing the neck in resecting the primary tumor (i.e. transcervical approach to the primary SCC), to decide when to electively treat the neck.¹⁷¹ In their series of 162 patients with oral or oropharyngeal SCC and N0 necks, 58 patients were observed and 104 patients received elective therapy in the form of a SND, radiation therapy, or a combination of the two. The decision to perform elective treatment of the neck was based on the clinical factors mentioned above, using 20% risk as the threshold for treatment. In their elective treatment group, 30% of the neck dissection specimens had evidence of metastatic disease, and 4% of the group, all of which had positive nodes on initial neck dissection, developed unsalvageable neck recurrences.

Elective neck dissection versus “wait and see” for the N0 patient

There are three prospective randomized trials that have compared the “wait and see” approach to the elective neck dissection and only one of them evaluated the use of the SND.^{166,184,185} Vandenbrouck *et al.* evaluated 75 patients, with primary SCC of the oral cavity and no evidence of nodal metastasis, that were randomly assigned to have either resection of the primary tumor without neck dissection or resection with a traditional radical neck dissection (RND).¹⁶⁶ The patients in both of these groups were kept on a monthly follow-up schedule for 3 years. In their series, they found that 49% had occult metastasis in the elective neck dissection group and that 47% of the patients in the “wait and see” group ultimately developed neck involvement and subsequently required salvage RND and radiation therapy. In the “wait and see” group, there was a higher incidence of extracapsular spread. Fakih *et al.* published a study of 70

patients, with T1 and T2 N0 oral tongue SCC, who were randomized into one of two groups: resection of the primary without elective neck dissection and resection of the primary and a RND.¹⁸⁵ These authors found that 57% of patients in the “wait and see” group developed neck metastasis and 47% of the patients in the RND group had histologic evidence of occult metastasis. At 1 year the disease-free survival (DFS) of the “wait and see” group was 52% while the DFS of the latter group was 63%, although this was not statistically significant.

The only prospective, randomized, controlled trial evaluating SND of levels I, II, and III as elective treatment for the N0 neck as compared to the “wait and see” approach was published in 1994 by Kligerman *et al.*¹⁸⁴ Their series included 67 patients with oral SCC and N0 necks, and they were randomly assigned to either resection of the primary alone or in conjunction with a SND of levels I, II, and III. These patients were followed for a minimum of 3 years postoperatively. The investigators found a rate of 21% occult metastasis in the elective SND group and a 39% rate of recurrence in the neck in the “wait and see” group. Critical to this study is the finding that only 27% were salvageable from the group of patients who developed neck recurrences. Kligerman *et al.* also reported that overall survival at 3 years was significantly improved in the elective neck dissection group.

Many retrospective, non-randomized studies have also reported on the benefits of the SND in treating the neck compared to the “wait and see” strategy.^{78,175,187,188,190} These studies are summarized in Table 34.2. Keski-Santti *et al.* found a significant improvement in survival despite more advanced primary tumors in the elective treatment groups, with 35% of patients in the observation group developing neck recurrences and only a 33% salvage rate.¹⁸⁸ Similarly, Capote *et al.* found an 8% neck recurrence rate in the elective neck dissection group versus a 26.8% rate in the observation group with a 5-year survival rate of 91.7% and 77%, respectively.¹⁷⁵ Again,

Table 34.2 Summary of data from retrospective observational studies on elective treatment of the N0 neck

Study	Elective therapy	Total patients	Occult metastasis on END ^a	Regional involvement on observation	Salvage ^b	Rate of DFS ^c
Khafif <i>et al.</i> 1991 ¹⁹⁰	RND	590	23%	19%		
Nieuwenhuis <i>et al.</i> 2002 ⁷⁸	N/A	161	N/A	21%	(79%)	79% at 12 months
Duvvuri <i>et al.</i> 2004 ¹⁸⁷	SND	359	23% (8%)	27%	Not reported	66% (54%) at 3 years
Keski-Santti <i>et al.</i> 2006 ¹⁸⁸	SND, RT or SND + RT	80	34% (13%)	24%	11% (47%) ^d	82% (81%) at 3 years
Capote <i>et al.</i> 2007 ¹⁷⁵	END	154	Not reported (8%)	26.8%	32% ^e	92.5% (71.2%) at 5 years

^a END, elective neck dissection. Numbers in parentheses indicates neck recurrences following END.

^b Salvage rates in neck recurrences only, unless otherwise noted. Numbers in parentheses indicate salvage rates for neck recurrences in observation group. Minimum follow-up time shown.

^c Numbers in parentheses indicate DFS in observation group.

^d Overall salvage rate for local and regional recurrences.

^e Neck salvage rate for both observation and END groups.

success of salvage therapy was low at 32%. In another non-randomized retrospective review of 359 patients, Duvvuri *et al.* found a 27% regional failure rate compared to 8% in the elective neck dissection group, although there was no difference in survival at 5 years.¹⁸⁷ Elective radiation therapy has also been shown to improve outcomes when used to manage the N0 neck.¹⁸² In a retrospective review of 354 oral cancer patients, Ord *et al.* reported a much higher neck salvage rate than the studies listed above at 50%.¹²²

A few studies have concluded that the “wait and see” approach to the neck is acceptable.^{78,190–192} Khafif *et al.*, in a retrospective analysis of 590 patients, found that patients with occult metastasis who received an elective RND did not gain a survival benefit when compared to those patients who were observed and subsequently developed clinically apparent nodal involvement with subsequent salvage RND.¹⁹⁰ Khafif *et al.* made the incorrect assumption that pathologically N0 (pN0) necks did not harbor occult metastasis. However, as will be discussed below and as is evident in the 7% neck recurrence rate among patients with pN0 necks in their study, this assumption is not accurate. When the elective RND group was analyzed, with both pN+ (pathologically positive for nodal involvement) and pN0 patients included, their survival was significantly improved over the salvage rate in the observation group, 68% with DFS compared to 49% with DFS, respectively. Khafif *et al.*’s recommendation not to electively treat the neck was based on the assumption that elective treatment would be with either RND or radiation therapy, both of which carry significant morbidity. Layland *et al.*, in a retrospective study of 891 patients with oral SCC and N0/N+ necks, showed that DFS was equivalent whether treatment of the neck was given electively or after nodal disease became apparent.¹⁹¹ One criticism of this study is that the observation arm has a higher percentage of early T1 disease as compared to T2–T4 disease, a discrepancy that was not statistically addressed and could have confounded the outcome and the final recommendation.

In consideration of each of these studies the reader must keep in mind that histopathologic review of nodes is not infallible. In most clinical pathology laboratories lymph nodes are bisected and evaluated for metastasis. Several studies have found a high prevalence of micrometastases, that is foci of tumor within lymph nodes smaller than 3 mm, when lymph nodes were serially examined with significantly thinner sections.^{193,194} When lymph nodes were evaluated in this manner micrometastases were identified in 16–25% of previously pathologically staged N0 necks. Therefore, it is likely that previous studies on the prevalence of occult metastasis discovered by elective neck dissections grossly underestimated the actual prevalence of nodal involvement, and that many of these neck dissections are actually therapeutic. This may explain the improved survival rates seen in elective treatment groups in several studies.^{184,188}

Quality of life for patients having a neck dissection

Since the time of Weiss *et al.*’s publication, the use of the SND has supplanted RND as the elective treatment of choice for the neck.^{163,164} Quality-of-life studies using general wellness and shoulder function specific assessments have demonstrated that the SND, when restricted to levels I–III, is not a significant detriment to quality of life, with outcomes in neck dissection patients nearly equal to those in patients who did not receive neck dissections.^{195–199} Patients who are treated with a radical neck dissection or a modified radical neck dissection (MRND) suffer a significant impact on quality of life including long-term dysfunction, disfigurement, and increased shoulder pain.²⁰⁰ Taylor *et al.* used the Neck Dissection Impairment Index to show that the greatest factors that affected quality of life, in descending order of significance, were age and weight, radiation therapy, and the extent of neck dissection.¹⁹⁶ Similarly, Rogers *et al.*, using the University of Washington Quality of Life scale coupled with the Neck Dissection Impairment Index and Shoulder Disability Questionnaire, found that patients treated with MRND or RND had the worst scores while patients who had a SND of levels I–III had similar scores to those patients who had no neck dissection.¹⁹⁵ Therefore, with the relatively low morbidity of SND compared to RND, the desirability values in the decision tree would certainly be different. Quality of life must also be considered for the patient who is followed using the “wait and see” approach and subsequently develops neck metastasis. Salvageable patients will be obligated to undergo a RND, possibly with chemo-radiation therapy.^{165,186,201,202} Thus, when the “wait and see” approach is used, failure will result in decreased survival and quality of life. Of course, elective treatment is only advisable if it effectively prevents recurrences and decreases cancer-related mortality. Most studies on SND demonstrate that it is efficacious in preventing neck recurrence and controlling occult neck metastasis.^{28,184}

Radiation therapy should not be used to treat the N0 neck

Radiation therapy has been proposed as an efficacious method to manage the N0 neck.¹⁸² The advantages of surgery for management of the N0 neck in patients with oral SCC are clear. While radiation therapy has been shown to be effective in treating oropharyngeal, nasopharyngeal, hypopharyngeal, and laryngeal SCC, it has compared unfavorably to surgery as a primary therapy for oral SCC due to its considerable morbidity and poor cancer control rates.^{203,204} Toxicities of radiation therapy include mucositis, xerostomia, and its dental sequelae, erythematous skin changes, subcutaneous fibrosis, carotid artery stenosis, and osteoradionecrosis.

Furthermore, speech and the ability to swallow are often more severely affected with radiation therapy. These adverse reactions lead to a protracted recovery that likely contributes to the lower quality-of-life scores that are correlated with radiation therapy.^{196,205,206} As surgery is the treatment of choice for primary oral SCC tumors and SND is better tolerated by patients when compared to radiation therapy, it is logical to prescribe SND rather than radiation therapy for the N0 neck in patients with oral SCC.

Despite treatment with curative intent, oral SCC has a relatively high recurrence rate. The use of radiation therapy as a primary therapy precludes its future use as adjunctive or salvage therapy. Operating in an irradiated field is technically challenging, making the salvage surgery more difficult with increased risk for complications. Radiation therapy should therefore be reserved for adjunctive or second line therapy in patients with oral SCC.

One of the prime reasons to choose surgery over radiation therapy for treatment of the N0 neck is the staging information that histopathologic review of the neck specimen provides.^{119,207} Although there are limitations to the accuracy of lymph node staging, as mentioned above, the histopathologic review of the neck is invaluable. Identification of extracapsular spread (ECS) and multiple occult nodes can significantly alter prognosis and signals the need for adjuvant treatment.^{167,173}

Extent of neck dissection for the N0 neck

When oral cancer metastasizes to the cervical region it metastasizes predictably to certain lymph node

groups. Since Crile's description of the neck dissection in 1906, treatment of the neck has evolved to become less radical and more conservative, including the sparing of non-lymphatic structures such as the spinal accessory nerve, the sternocleidomastoid muscle, and the internal jugular vein. Also, the number of lymph node levels that are dissected has decreased with no change in outcome.^{163,179,208} Limiting the dissection to the node levels and structures that are at greatest risk has led to a marked reduction in postoperative morbidity, particularly with avoiding sacrifice of the spinal accessory nerve and avoiding trauma to this nerve by foregoing dissection of the posterior triangle.¹⁹⁸ For the N0 oral SCC patient levels I–III should be removed.¹⁶⁴ Fig. 34.17 illustrates the levels of neck as classified in 2002 by Robbins *et al.*²⁰⁹

The anatomic limits of the SND are based on studies that have shown that oral SCC follows predictable patterns of lymphatic metastasis.^{28,164,210–213} Lindberg's classic study of 1972 demonstrated that oral cavity SCCs metastasize to the submandibular triangle, the submental triangle, the upper jugular chain, and the mid-jugular chain of lymph nodes.²¹² Lindberg also described the prevalence of "skip metastases" in his series, where metastatic tumor could "skip" the upper echelon of nodes, i.e. the jugulodigastric or submandibular nodes, and be found in the mid-jugular chain. These skip metastases were rarely found in the lower jugular chain (level IV) or in the posterior triangle of the neck (level V). Several subsequent studies have confirmed Lindberg's observations. Shah *et al.* found in a series of 1119 RNDs for primary oral SCC tumors, level V nodes were never involved when levels I–IV were negative.¹⁶⁴ Davidson

Fig. 34.17 Illustration of the levels and sub-levels of the neck. Notice that level II is divided into IIA and IIB by the spinal accessory nerve and level V is divided by a horizontal plane from the inferior border of the cricoid arch into VA and VB.

et al., in a cohort of 1123 patients with head and neck SCC, reported that only 1% of their patients staged clinically as N0 had metastasis to level V.²¹⁰ In 2004, Dias *et al.* published a series of 339 patients in which only 1.5% of patients with N0 necks had skip metastasis to level IV, and no patients had skip metastases to level V.²¹¹ The efficacy of SND relative to RND has been studied and the two modes of dissection have similar efficacy.^{28,169,174,184,187,214}

The reclassification of the neck levels by Robbins *et al.* divided level II into IIA and IIB using the spinal accessory nerve as the dividing line, and level V into VA and VB using a horizontal plane that crosses the inferior border of the anterior cricoid arch as a dividing line.²⁰⁹ The purpose of this reclassification was to distinguish sub-levels IIB and VA for potential preservation. The rationale behind this decision was based on the premise that IIB nodes (also known as the supraretrospinal triangle, supraspinal accessory lymph node pad, or the submuscular recess) were rarely involved in occult metastasis and that dissection of those nodes may lead to traction of the spinal accessory nerve and subsequent shoulder dysfunction.²⁰⁰ Several studies have confirmed that metastases to level IIB are relatively rare. Silverman *et al.* only found 1.6% of 74 patients with IIB metastasis.²¹⁵ Elshiekh *et al.* found no positive IIB nodes using reverse transcriptase polymerase chain reaction (RT-PCR) molecular techniques, except in SCC of the oral tongue.²¹⁶ In this sub-site, they found 10% of patients had molecular evidence of tumor cells in IIB nodes. Lim *et al.* also only found 5% of metastasis to this level in 74 of their patients.²¹⁷ Level IIB should generally be included in the neck dissection. Metastasis to this sublevel does occur and there are no quality-of-life studies demonstrating the benefits of preservation of level IIB. If neck salvage is required completion neck dissection to include level IIB in the setting of recurrence, previous surgery, and possible radiation will be much more difficult and place the spinal accessory nerve at increased risk than if level IIB had been dissected at the time of the initial surgery. Dissection of level IIB is therefore recommended at the time of elective neck dissection (Fig. 34.18).

Contralateral occult metastasis is also observed, particularly in tumors that encroach on the midline.²¹² It is recommended that a SND be prescribed bilaterally for patients with oral SCC that violates the midline.²⁰⁹ This includes any SCC tumor that requires a wide resection that crosses the midline in order to achieve a 1 cm margin.

Sentinel node biopsy

Perhaps the best example of the shift towards ultra-selectivity in management of the N0 neck is the application of the sentinel node biopsy technique. The sentinel lymph node biopsy technique involves injection of radiolabeled tracer around the periphery of the tumor, allowing the tracer to drain via the lymphatic system to the first echelon of nodes. The sentinel node or nodes are then delineated using a gamma probe, followed by the surgical removal of the node(s) in a manner that is oncologically safe. These nodes are then examined by frozen section. If micrometastases are identified on frozen section, the patient receives a SND. Postoperatively, the nodes from the permanent specimen are then examined thoroughly by serial sectioning, as opposed to bisectioning, which is the technique typically used to sample lymph nodes for histopathologic review. If micrometastases are located in the permanent serial sections, the patient is brought back to the operating room for a conventional SND if it has not already been performed.²¹⁸

Fig. 34.18 Dissection of neck level IIB. Careful dissection of level IIB with preservation of the spinal accessory nerve should be performed when performing a selective neck dissection. While level IIB is an uncommon site of metastasis from an oral cavity, primary surgical salvage of neck failure involving level IIB is technically arduous and often unsuccessful.

This technique, which has been used effectively in the treatment of melanoma and breast cancer, has been advocated for treatment of the N0 neck in oral SCC. Preliminary results from a multicenter trial in 2004 were favorable.²¹⁹ In addition, a recent clinical trial published by Stoeckli *et al.* demonstrated that the use of sentinel node biopsy had very high sensitivity and specificity for detecting occult metastases, with a false-negative rate of only 6%.²¹⁸ In addition, in nine patients (13%) with laterally located floor of mouth and oral tongue SCC, the use of sentinel node biopsy identified drainage to contralateral nodes and level IV nodes, regions that would not have been addressed by a conventional SND. There have also been some concerns regarding the use of sentinel node biopsy in the management of the N0 neck. The radiolabeled tracer which is injected into the oral SCC tumor, especially tumors involving the floor of mouth and oral tongue, would obscure gamma probe readings in the first echelon nodes due to their proximity to the primary tumor, negating any benefit from the exercise. Stoeckli *et al.* attempted to circumvent this problem by going against conventional practice and excising the primary tumor first, before the sentinel nodes

were marked out and addressed.²¹⁸ Another criticism of the sentinel lymph node technique is that if micro-metastasis is detected later after serial sectioning of the permanent specimen, the patient would be required to undergo a second surgery. Knowing the high rates of occult metastasis, this would likely result in 20–45% of patients requiring second surgeries. The studies that have been published evaluating the efficacy of this technique are small. More studies will need to be done before the efficacy of sentinel node biopsy can be adequately compared to the conventional SND with its attendant low morbidity. Removing level I and II nodes is not significantly less morbid than removing levels I–III; however, performing two separate operations instead of one certainly is more morbid. Although the sentinel node biopsy warrants further investigation, it is still too early to recommend it as a treatment for the N0 neck.

Managing the N+ neck

For the patient with clinically palpable nodes a fine-needle aspiration can be performed to determine if there is malignant involvement of the neck. If neck involvement is either suspected or confirmed then a MRND with preservation of the spinal accessory nerve should be performed. Appropriate muscle flap coverage of the carotid artery with a scalene muscle should be considered, especially if the patient is to receive postoperative radiation therapy. Preservation of the internal jugular might be required for free flap reconstruction. Sacrificing the spinal accessory nerve should be reserved for cases where there is direct involvement of the nerve with carcinoma. Shoulder dysfunction is a common complaint following neck dissection. Complications following neck dissection, while rare, include hematoma, lymphalocele, ear numbness, and shoulder dysfunction. Given that ear numbness is one of the primary complaints following neck dissection, the greater auricular nerve should be preserved if possible.

There is no standard in terms of number of lymph nodes harvested for a neck dissection. The count will depend on the levels dissected and the attention to detail of the surgeon as well as the pathologist. What must be considered when reviewing the pathologic status of lymph nodes is that in many centers the lymph nodes are only bisected and the chance of missing metastasis is high.

Postsurgical management

Histopathologic evaluation of the specimen

Following the resection the primary oral SCC specimen and neck should be pinned out and oriented for the pathologist. Such orientation will help with pathologic evaluation of the margins, as well as the

neck (Fig. 34.19). Following surgery the pathology report should be carefully reviewed and the critical features to evaluate are marginal status, perineural infiltration, lymphovascular involvement, lymph nodes involved, and extracapsular spread of involved nodes. Consideration should be given to margin shrinkage that occurs with processing.¹⁰⁰ The surgeon is sometimes faced with the uncomfortable situation of how to handle a truly positive margin (carcinoma at the resection margin). Further resection will often produce a negative pathology report.

The decision for postoperative radiotherapy will be based on both margin and neck status. As discussed previously there is not a clear definition among clinicians, pathologists and investigators regarding what is meant by “clear” and “close” margins, as well as the distinction between mucosal and deep margins.^{38,90,95,97} While surgeons typically try to resect oral cancer with a 1 cm margin of clinically normal tissue, pathologic evaluation of the specimen almost always demonstrates significantly less normal tissue surrounding the cancer. This reduced margin can partially be explained by tissue shrinkage that occurs with specimen processing. A study in dogs demonstrated that 30–50% tissue shrinkage (from clinical to histologic margin) occurs with specimen processing.²²⁰ Another issue that can compound the interpretation of margins and studies evaluating margins in oral cancer is the site of the primary cancer. Woolgar *et al.* has demonstrated that the oral cancer sub-site significantly impacted on the status of the margins.³⁸ Using the definition of 1 mm margin as an involved margin these authors showed that the percentage of involved margins was highest in maxillary alveolar (45%), retromolar (38%), buccal mucosa (33%), mandibular alveolus (17%), and tongue SCC (11%).³⁸ Not surprisingly, the incidence of involved margins increased with the tumor T stage in this study.³⁸ Even when histologic margins are clear, recurrences occur and are most likely secondary to

Fig. 34.19 Bilateral resected neck specimen pinned out and labeled prior to pathologic processing. Labels have been placed to designate levels 1 through 4. Nodes that are clinically suspicious for harboring SCC are marked out. By orienting the specimen the pathologist is able to more accurately determine which cervical levels are involved. Precise pathologic information is key to planning postoperative radiation therapy.

retained histologically normal but genetically altered mucosa.¹⁰¹ As molecular technology advances in terms of efficiency and sensitivity, it is anticipated that molecular margin analysis will significantly improve surgeons' ability to obtain both histologically and genetically clear margins.

Postoperative complications

A retrospective study on 242 patients older than 70 showed that in older patients predictive factors for postoperative complications include male sex, bilateral neck dissection, two or more comorbidities, and clinical stage IV.²²¹ Patient's age alone is not an indicator of surgical outcome, rather comorbidities and time under general anesthesia are predictors of postoperative complications and hospital length of stay.²²² A study focused on oral cancer found that the operative death rate was slightly higher than 3.2%. Factors which could be used to predict postoperative complications included pre-existing cardiovascular and respiratory disease, alcohol consumption, stage of disease, scale and duration of surgery, tracheostomies, poor differentiation of tumor, and presence of extracapsular spread of carcinoma.²²³ Perioperative stroke in patients having a neck dissection is rare.²²⁴ While studies on head and neck cancer give us less specific information regarding perioperative complications the results can be helpful in preventing complications and improving patient outcome. A review of 3932 patients undergoing head and neck surgical procedures showed that the overall medical morbidity and mortality rates were 5.65% and 2.98%, respectively.²²⁵ The presence of a major medical complication increased the odds of death by 5.65. Postoperative pneumonia was the most common medical complication. Acute myocardial infarction and stroke were rare and were not associated with increased mortality. Prophylactic antibiotics should cover aerobic, anaerobic, and Gram-negative bacteria. Methicillin-resistant *Staphylococcus aureus* infection is devastating in patients undergoing major head and neck surgery.²²⁶ Perioperative complications can be minimized by careful control of blood pressure and heart rate, deep venous thrombosis prophylaxis, and early mobilization.

Surgery and postoperative radiation

The role of radiation therapy in the management of oral cancer is adjuvant. As discussed previously oral cavity SCCs are poorly responsive to radiotherapy as primary treatment.^{151,204,227} Surgical salvage, frequently required following radiation therapy, is extremely difficult and postoperative complications are more frequent and more difficult to manage. Preoperative radiation therapy is not given for oral cavity carcinoma. In certain cases preoperative radiation therapy, in the dose range of 50 Gy, is used for sinonasal or paranasal carcinomas to improve resect-

ability. Preoperative radiation therapy is associated with wound healing complications. The surgical margins would not change following radiation therapy for oral cavity carcinoma. If the well informed patient refuses surgery or is deemed not to be able to tolerate surgical resection, primary radiation therapy can be considered for palliation. The patient should be involved in the decision regarding radiation therapy and it is critical for the patient to be aware of the progressive, life-long side-effects that result from radiation therapy.

Possible indications for postoperative radiation therapy include positive or close margins, perineural invasion, extensive bone invasion, and neck involvement (strong indication for more than one lymph node involved or extracapsular spread). While these recommendations are commonly used, each case must be evaluated independently and there is not universal agreement on these indications.²²⁸ For patients with stage III and IV oral SCC, postoperative radiation therapy improves control of the carcinoma, particularly in the setting of positive margins. A classic paper demonstrating improved disease control was published by Vikram *et al.* in 1984.⁹¹ Even when the authors viewed the margins as satisfactory, recurrence occurred in 39% of the cases compared with 73% of cases when the margins were positive. Recurrence rates were significantly reduced to 2% and 10.5%, respectively, with postoperative radiation therapy. However, the study suffers from a lack of control of variables. Some of the patients received postoperative chemotherapy. The study also included SCCs from multiple head and neck sites, including oral cavity, oropharynx, hypopharynx, and larynx. Loree *et al.* retrospectively evaluated 398 patients treated for SCC and evaluated the impact of surgical margin status, with and without postoperative radiotherapy, on recurrence.⁹⁵ Postoperative radiotherapy did not significantly lower recurrence rates in patients with positive surgical margins. This study concluded that postoperative radiotherapy is relatively ineffective in local control in patients with positive surgical margins. A more recent study looking at 425 patients with oral cavity SCC showed that positive surgical margins increased the risk of death at 5 years by 90%, after controlling for significant prognostic factors.²²⁹ These studies confirm that of all the factors impacting oral cancer patients' outcome, the surgical margin, which is under the direct control of the surgeon, is one of the most critical.

Intensity modulated radiation therapy (IMRT) represents a significant technological step forward in the management of head and neck SCC. IMRT with parotid sparing has been shown to result in less xerostomia, as measured by a validated xerostomia questionnaire, compared to conventional radiation therapy.²³⁰ This study, however, combined multiple head and neck sites with the oropharynx as the single most common site in this study. Radiation therapy in

the form of electrons can be used to boost the neck. This approach treats superficial tissue in the neck and avoids damage to the spinal cord.

Timing of radiation therapy is critical and should be started as soon as possible following healing. Multiple studies have demonstrated that recurrence rates increase when there is a delay in starting radiation therapy. A delay of greater than 6 weeks after surgery leads to increased recurrence rates.⁹¹ The surgeon needs to not only consider the interval between surgery and radiation therapy but the overall duration of the “treatment package”. Locoregional control of oral cavity cancer improves if the duration of all treatment is less than 100 days.²³¹ Breaks in radiation therapy should be avoided in all cases unless the patient’s health is at significant risk. Patients will often require diligent care of the surgeon and radiation oncologist to get them through radiation therapy without a break.

Chemotherapy and radiation therapy

The addition of chemotherapy to radiation therapy has improved both locoregional tumor control and survival rates. The Radiation Therapy Oncology Group 9501 was designed to determine whether concurrent cisplatin therapy and postoperative radiotherapy improve the rates of local and regional control among patients who have high-risk operable head and neck cancer.²⁰² High risk was defined as having any of the following: histologic evidence of invasion of two or more regional lymph nodes, extracapsular extension of nodal disease, and microscopically involved mucosal margins of resection. A total of 416 patients were enrolled. A significant increase in severe adverse side-effects (primarily hematologic, mucous-membrane, and gastrointestinal) was observed. Most importantly, concurrent postoperative chemotherapy and radiotherapy significantly improved the rates of local and regional control and disease-free survival.

A parallel, randomized trial consisting of 334 patients by the European Organization for Research and Treatment for Cancer (EORTC) commenced to test whether adjuvant chemotherapy and radiotherapy improves progression-free survival, overall survival, and local or regional control more than does radiotherapy alone in patients with stage III or stage IV head and neck cancer.²⁰¹ Patients with oral cavity SCCs comprised 87 of the subjects. This trial demonstrated that high-dose cisplatin with radiotherapy significantly increased the rates of local control, disease-specific survival, and overall survival. There was not an increase in late adverse effects.

In each of the above trials cisplatin was the chemotherapeutic agent. Cisplatin is delivered intravenously over 1 to a few hours. It is typically prescribed in a dose of 100 mg/m² of body surface area. In the above trials cisplatin was given three times during radiotherapy (days 1, 22, and 43). The primary complica-

tion is nephrotoxicity but is prevented with hydration before and after treatment.

Follow-up

Most recurrences and locoregional failures will occur within the first 2 years. Follow-up appointments are recommended every month for the first year, every 2 months for the second year, every 3 months for the third year and every 6 months thereafter. There is little available data to guide the surgeon in making evidence-based decisions regarding interval imaging. This decision should be made by the surgeon based on the clinical behavior of the cancer and the pathologic findings. Patients with oral cancer are at risk for second primaries. The risk for a synchronous or metachronous second head and neck primary in patients with oral SCC ranges is 21%, a rate that is higher than patients with pharyngeal or laryngeal SCC.²³² A long-term, large-scale phase III trial evaluating low-dose isotretinoin had no effect on the rates of second primary tumors or smoking-related second primary cancers.²³³ This study did show a substantial impact of smoking on the development of second primary tumors and survival.²³³ Therefore, an aggressive smoking cessation program should be implemented with oral cancer patients who continue to smoke. A 6-monthly chest radiograph as a routine follow-up examination for patients with oral SCC has no clear benefits.²³⁴

Non-resectable SCC or poor surgical candidates

The question is often raised of what to do with an elderly patient with a limited life expectancy. It is often a mistake to not treat the cancer since many of these patients will live much longer than expected and if the cancer is not treated patients will develop significant pain. Surgical resection provides significant relief of the pain.⁶¹ Palliative chemotherapy or chemoradiation should always be considered. A randomized phase III trial evaluated head and neck cancer patients who had stage III or IV disease with no distant metastasis and had tumors considered unresectable.²³⁵ For patients with unresectable head and neck SCC, induction chemotherapy (cisplatin, fluorouracil and docetaxel) followed by chemoradiation (with weekly carboplatin) improves overall survival.²³⁵

Summary

Oral cancer is a surgical disease. Quality-of-life studies have now clearly demonstrated that our patients’ perception of success is different than ours as surgeons. Patient survival is a facile endpoint which is no longer acceptable. Patients must be restored to

near complete function. A thorough and comprehensive understanding of oral function, particularly dental expertise with appropriate training to preserve and restore the preoperative occlusion and jaw relationships, will provide patients the outcome that they are seeking. Cancer resection should be driven by oncologic principles of clear margins. In terms of reconstruction patients should only have more complex reconstruction if it has a clear improvement of function. For example, microvascular reconstruction of a partial glossectomy defect after surgical resection of a T1 tongue SCC must provide the patient with a meaningful improvement in function over a split-thickness skin graft. Austere attention to detail with preoperative planning, intraoperative decision making, and postoperative care, as well as a rigorous, life-long devotion to the care of his or her patients, is the minimum standard expected of the oral and maxillofacial surgical oncologist. The surgeon must assume the role as director of the multidisciplinary team in the management of the oral cancer patient. This role carries with it the responsibility to maintain a contemporaneous, functional fund of knowledge in all areas of oral cancer management including cancer detection, adjuvant therapy, medical management of the postsurgical patient, and molecular biology. The discovery of new knowledge, which should be surgeon driven, will be the most effective method to reduce, and ultimately eliminate, the burden of disease borne by the oral cancer patient.

Chapter 35

Management of Patients Undergoing Radiation and Chemotherapy

Göran Kjeller

This chapter describes the types of tumor and the criteria for treating them with radiation therapy alone, radiation therapy combined with surgery, radiation therapy combined with chemotherapy, and radiation therapy combined with both chemotherapy and surgery. The different protocols available for the different types of tumor will be described, including the different order in which they may be given. The side-effects of radiation therapy and chemotherapy are described as well as the long-term oral complications from both types of therapy.

Cancer in the head and neck region is relatively uncommon, although approximately 644 000 new such cancers are diagnosed each year on a worldwide basis.¹ Approximately two thirds of these cancers occur in the developing world. In the US head and neck cancer accounts for around 3.2% of all new cancers and 2.2% of all cancer deaths.¹ The incidence of head and neck cancer is about three times higher in men than in women.²

Lesions of squamous cell origin are the most common (>90%) of all head and neck cancers, and they are found in the lips, oral cavity, naso-, oro-, and hypopharynx, as well as in the larynx. Notably, during the last decade, cancer in the tonsils and the base of the tongue has increased in frequency, especially in the younger population.³ Cells with origin in the salivary glands may also be observed among head and neck cancers, resulting in adenocarcinomas, mucoepidermoid carcinomas, adenoid cystic carcinoma,

mas, acinic cell cancer, and malignant pleomorphic adenoma. Malignant melanomas and other tumor types are rarely seen.

Among the known etiological factors for oral cancer, smoking and alcohol abuse are the most common. A heavy smoker has a 5–25-fold higher risk of developing cancer in the head and neck region, compared to non-smokers.⁴ An increasing number of reports also indicate that different types of viruses, e.g. human papilloma virus (HPV) and Epstein–Barr virus (EBV), may cause malignancies.

During the treatment of head and neck cancers, many medical disciplines may be involved, i.e. ENT (head and neck) surgeons, maxillofacial surgeons, and oncologists. The treatment program for head and neck cancers differs between different centers worldwide depending on available techniques, tradition, and results. However, the primary goal of any treatment is survival, and the secondary goal is restoration of function and esthetics.

Prior to the decision of which treatment each unique cancer should be subjected to, several investigations are usually performed. Among them, histological examination of samples of the tumor is the most important. Cytological examination of lymph nodes may be a complement to the histology. Computed tomography (CT) scan and magnetic resonance imaging (MRI) are also important to elucidate the extent of the tumor as well as of any regional or distant spread of the cancer. Sometimes palpation of the area as well as inspection using some type of optical instrument may be necessary. A positron emission tomography (PET) scan may be of use to identify a primary tumor in cases where regional metastasis is the first sign of the disease, as well as to detect any recurrences. It can also be used to evaluate the result of treatment. The results are used for classification of the respective carcinoma (Tables 35.1 and 35.2), and also for treatment planning according to the principles at each center or in each country.

An evaluation of the respective patient's general health is also essential in order to evaluate which treatment is the most suitable.

Table 35.1 TNM classification for head and neck cancer. T staging is, however, not valid for nasopharynx, salivary gland carcinoma and laryngeal carcinoma.

Class	Primary tumor (T)	Regional nodal (N)	Distant metastasis (M)
X	Primary tumor cannot be assessed		
0	No evidence of primary tumor	No regional nodes can be assessed	No distant metastasis can be assessed
1	Tumor ≤ 2 cm in the greatest dimension	Single ipsilateral lymph node, less than ≤ 3 cm	Distant metastasis
2	Tumor > 2 cm but < 4 cm in the greatest dimension	a: Single ipsilateral 3–6 cm b: Multiple ipsilateral ≤ 6 cm c: Bilateral or contralateral lymph node ≤ 6 cm	
3	Tumor > 4 cm in the greatest dimension	Ipsilateral or contralateral lymph node > 6 cm	
4	Tumor invades adjacent structures		

Table 35.2 Staging of carcinoma.

Stages	
I	T1N0M0
II	T2N0M0
III	T3N0M0/T1–3N1M0
IV	T4N0M0/T4N1M0/T1–4N2–3M0/T1–4N0–3M1

Generally, however, it can be stated that early stage cancers (I and II) can be treated with either surgery or radiotherapy with comparable results. The anatomic location of the cancer may be the factor that determines if radiotherapy or surgery is to be used; the opportunities for reconstruction and the patient's quality of life must also be considered. For instance, a T1 or T2 tumor of the nose, external ear or the lip may be better treated with radiotherapy rather than surgical resection for esthetic reasons.

A combined approach of both surgery and radiation therapy may be preferable for intermediate stage (III) carcinomas. The order of treatment, i.e. if the radiotherapy is pre- or postoperative, differs between countries and centers on a worldwide basis.

In patients with local late-stage tumors (IV), a combination of chemotherapy, radiotherapy, and surgery may be the treatment of choice. If the cancer is not resectable or if an organ is to be preserved, chemotherapy and radiotherapy are frequently used initially and then surgery may be used either to complement the treatment or as salvage treatment. In other cases, when the tumor is resectable while preserving an acceptable level of function and esthetics, or when reconstruction is possible, the treatment can begin with surgical resection, to be followed with radiotherapy.

Radiotherapy

The aim and purpose of radiation therapy in the treatment of head and neck cancer may be two-fold:

- the target (cancer) is either a primary tumor or with regional spread to the regional lymph nodes;
- the target is clinically and radiologically tumor-free lymph nodes of the neck, but with a high risk of micrometastasis.

Occasionally radiotherapy may also be used to treat benign tumors, such as ameloblastomas or pleomorphic adenomas, when other treatments may be detrimental.

The intention of radiotherapy may either be curative or palliative. When the intention is to cure the patient from the disease, the radiation may be given either as a single modality if the cancer is small, i.e. stage I and II, or as a complement to surgery. When combined with surgery, it may be given prior to, or after surgery. Radiotherapy can also be given in combination with chemotherapy, with a curative intention. When the radiotherapy has a curative intention, the radiation is given at small doses (1–2 Gy) once or twice a day for a period of 3–7 weeks.

When the cancer is not curable, the intention of radiotherapy may be palliative, i.e. it can be used to reduce the symptoms of the disease, e.g. reducing pain emanating from skeletal metastasis, relieving pressure on vital organ systems. When the radiotherapy has a palliative intention, higher doses are given each time, to reach an effect faster. Palliative radiotherapy can improve the quality of life during the last months of life of a patient with an incurable cancer.

Radiation involves the transport of energy, either as electromagnetic waves (photons) or as a beam of particles (electrons or protons). The position of the tumor determines which type of radiation to be used. Particle beams normally have a shorter range, implying that such radiation is used when the cancer is located relatively superficially in the tissues. In contrast, photon radiation is used when the tumor is located more deeply in the tissues.

When radiotherapy is given as a single modality therapy, a lower dose is given to local lymph nodes in order to prevent and sterilize micrometastasis and a

higher dose is administered to the known primary tumor, i.e. the cancer. If, on the other hand, radiation is combined with surgery, a smaller dose is given with the aim of sterilizing potential micrometastasis in local lymph nodes.

Conventional radiotherapy implies that the primary tumor as well as the larger lymph nodes of the neck are irradiated with up to 70Gy. The radiation is given in single fractions of 1.8–2.0Gy on a daily basis for 6–7 weeks.

Altered fractions have recently been shown to achieve better control both locally and regionally. Hyperfractionation is where 1.2Gy is given twice a day for about 6–7 weeks, and accelerated fractionation means that 1.6Gy is given twice a day for about 6 weeks. A third alternative may be accelerated fractionation with a concomitant boost given as 1.8Gy a day for 6 weeks and during the last 12 days an additional 1.5Gy is given daily as the boost.

Recently a new form of radiotherapy has been introduced, IMRT (intense modulated radiotherapy). This technique is built on a computer-generated three-dimensional image which allows delivery of high doses of radiotherapy to clinical target volumes, still preserving some critical normal structures, for instance salivary glands.

Brachytherapy

Interstitial radiotherapy, or brachytherapy, is administration of irradiation by implantation of a radioactive material very close to, or inside, the primary tumor. A frequently used substance is iridium (^{192}Ir). The time-span of the treatment may vary between a few seconds to a few days, depending on the type of cancer.

Small tumors, without a risk of spreading to the regional nodes, may be treated with brachytherapy only. In cases where the tumor is of larger size or invades surrounding tissues or structures, as well as when there is a risk of spread to regional lymph nodes, brachytherapy is used to deliver a final boost to the primary tumor after an initial more moderate external dose. Brachytherapy is frequently used as the final part in the treatment of cancer in the base of the tongue and in the tonsils. Brachytherapy can also be used when there is a palliative intention, for instance in the treatment of laryngeal cancer.

Chemotherapy

The use of drugs in the treatment of head and neck cancer is still a matter of debate. Despite considerable research, there is no drug or combination of drugs available today that can cure solid cancers in the head and neck region. In general oncology, chemotherapy is given either to cure cancer, or to reduce the speed of progression, or to ameliorate the symptoms. Sometimes

chemotherapy is also administered to reduce the risk of recurrences, so-called adjuvant treatment.

Chemotherapy is generally used prior to (induction), or parallel (concomitant) to radiotherapy. The purpose of chemotherapy is to kill the cancer cells, or at least impede their growth.

Delivery of chemotherapy is made either by intravenous or oral administration. Different drugs are normally combined in different ways depending on the type of cancer to be treated. The drugs are normally given every second to every fourth week. Drugs frequently used are cisplatin, 5-fluorouracil (5-FU), and methotrexate.

It is necessary to repeat the treatment since all cancer cells are not killed at the same time. During the treatment of cancer in the head and neck region, it is normal to administer the drugs two to three times prior to radiotherapy, where the third treatment frequently is concomitant to radiotherapy. Prior to a new administration of drugs, blood counts are always analyzed. After a series of administrations of drugs, an analysis of the treatment is performed, often by a CT scan.

The drugs used in chemotherapy affect the cells in different ways. Some drugs are designed to affect the DNA. Other drugs interfere with the intracellular transporting systems. The aim of all drugs is, however, to result in apoptosis of the cancer cells. To achieve maximum effect, with as few side-effects as possible, different combinations of drugs are normally used.

An advantage with the use of chemotherapy is that the drug, as it is administered via the bloodstream, is able to affect cancer cells on their way to producing metastasis somewhere distant from the original tumor. A disadvantage with the use of chemotherapy is that none of today's available drugs are able to distinguish between cancer cells and normal, healthy cells, which means they also have effects on normal tissues. Among the normal tissues most affected by chemotherapy are tissues with a high turnover rate, i.e. bone marrow, hair, and mucosa, resulting in decreased blood counts, loss of hair, and gastrointestinal problems (nausea and diarrhea). Fortunately, the normal and healthy cells have a great capacity for recovery and repair of the DNA, resulting in complete or almost complete remission of the side-effects after termination of chemotherapy. This is the reason for interruptions in the chemotherapy schedule.

Side-effects

Radiotherapy

The side-effects of radiation therapy can be divided into acute, but mostly reversible effects, and late, more commonly irreversible conditions. The acute side-effects almost always decline within 4–6 weeks after completion of radiation, whereas the late effects

can develop after different periods of time and they will also almost always last for the rest of the patient's life.

Among the acute effects, an inflammatory reaction in the mucosa (Fig. 35.1) of the oral and pharyngeal mucosa – mucositis – is the most common. The appearance of the mucosa can vary from an increased redness, to an intense reddish appearance, to white necrotic lesions. The damage to the oral mucosa can also make it more susceptible to both bacterial and fungal infections. These conditions are almost always associated with varying degrees of pain, and may need relatively strong analgesics.

The skin reactions can vary between a tan-like appearance to almost burn-like (Fig. 35.2) wounds. Softening and lubricating lotions are recommended for the affected skin. Males should be recommended to use an electrical shaver in order to spare the skin as well as not to use aftershave, since the alcohol may add to dryness of the skin.

An increased production of sticky mucus can also be observed after radiation of cancers in the pharyngeal region. Both still and sparkling water seem to be effective in dissolving the mucus. The use of milk products should be minimized.

Fig. 35.1 Intraoral mucositis, degree 3–4, observed at the later stages of external, and after interstitial, radiotherapy.

Fig. 35.2 Clinical appearance of a burn-like wound of the skin after termination of external radiation therapy.

Nutritional problems are frequently seen, and are almost always a result of local reactions in the mucosa as well as of the pain. A loss of appetite may also be a result of loss of, or change of, taste. A majority of the patients undergoing radiotherapy to the head and neck region need professional assistance with nutrition. Some people may need some type of gastric tube to be able to feed themselves.

Tiredness and nausea are other side-effects which are frequently observed during radiotherapy.

Among the irreversible side effects observed after radiotherapy, xerostomia is the most common. The degree differs between different patients. A majority of all saliva is secreted by the large salivary glands, and frequently these glands are within the field of irradiation. A secondary effect of increased oral dryness may be an altered taste and increased sensitivity to different tastes. Some patients need to avoid some type of spices, for instance pepper. The mucosa can also be more sensitive to different types of food, i.e. its consistency. Xerostomia carries an increased risk for development of dental caries and other dental problems.

Radiation also decreases the elasticity of the tissues, which can result in both dysphagia and trismus. The negative effect of radiation on vessels is also well recognised; decreased vascularity can lead to necrosis of both the soft tissues and the bone within the irradiated area.

Chemotherapy

Chemotherapy is also associated with a number of side-effects. Loss of hair is the most well known side-effect of chemotherapy and is usually observed between 1–2 weeks after the treatment.

All mucous membranes are susceptible to chemotherapy due to the quick turnover of cells. Wounds and dryness of the mouth, nausea, and diarrhea may be the result of chemotherapy. Nausea is observed more often in women and younger people. The condition can, however, be reduced effectively with medications.

Loss of appetite is another side-effect, resulting in loss of weight. Professional nutritional counseling is frequently needed. It is, however, not unusual for a patient to gain weight during chemotherapy due to the fact that they may feel better with food in the stomach.

Another vital organ affected by chemotherapy is the bone marrow. The effect may be low blood counts for all types of blood cells, resulting in anemia, increased susceptibility to infections, and increased risk of spontaneous bleeding, e.g. nose bleeds and gingival bleeding. Transfusions may be necessary during chemotherapy.

Tiredness is also a frequently seen side-effect. Lack of energy and problems with concentration may be related to the tiredness. It is of great importance to

rest when necessary, to eat as good and well balanced food as possible, and to exercise.

The most positive fact related to chemotherapy is, however, that all side-effects almost always subside after termination of the treatment.

Management of oral health during radiation

Prior to the start of radiation therapy for treatment of head and neck cancers, it is of great importance to survey the oral health of the patient. A thorough oral examination, including radiographs, with special attention to marginal and apical periodontitis, calculus, and dental caries, is necessary. All infections should be treated, i.e. teeth may be either extracted or treated endodontically. Calculus should be removed, i.e. the teeth should be scaled and cleaned professionally. All caries should be excavated and the teeth should, at least, be supplied with temporary fillings. Daily rinsing with sodium fluoride solutions is recommended and prescribed to each patient as a complement to the use of fluoridated toothpaste.

By taking impressions of both the upper and the lower jaw, the dental technician can make casts on which different devices can be produced. These devices, the mouth-opening device (Fig. 35.3) and the mandibular protection device (Fig. 35.4), are used in order to reduce the effect of irradiation on, or to protect, the surrounding tissues not in need of treatment. The casts can also be used to produce trays (Fig. 35.5) to administer high-concentration (0.2%) sodium fluoride gel on a daily basis.

The mouth-opening device can be designed with and without a tongue depressor. A device without a tongue depressor is used during the radiotherapy when the cancer is located in the floor of the mouth, in the submandibular gland, or in the chin. In contrast, a device supplied with a depressor is used when the cancer is located in the tongue, in the base of the tongue, in the maxillary sinus, in the nose, in the

Fig. 35.3 A clinical picture of a patient with a mouth-opening device used to protect parts of the head in no need of radiation.

upper lip, in the palate, and sometimes also in the floor of the mouth.

The mandibular protection device is used during interstitial radiotherapy to displace the tongue, the cheek or the lip away from the implanted radiation source. It also protects the mandibular bone. This device is used during interstitial radiation of carcinomas in the tongue, the base of the tongue, the tonsils, the floor of the mouth, and the lips. The mandibular protection device is made of approximately 6 mm thick plastic with 2 mm of lead included. The device can also be used to protect the bone of the maxilla, although it is most frequently used to protect the mandible.

During the period of radiation, at least weekly professional cleaning of the teeth and mouth is recommended. As treatment continues, i.e. radiation accumulates within the tissues, the patient will have more discomfort, making it hard to maintain proper oral hygiene.

Management of oral health during chemotherapy

As with patients scheduled for radiotherapy, it is important to thoroughly examine the oral health of

Fig. 35.4 A clinical picture of a patient wearing a mandibular protection device used during interstitial radiation (brachytherapy).

Fig. 35.5 A clinical picture of a patient wearing fluoride gel trays.

patients who will receive chemotherapy. An individual treatment plan should be determined for each patient. The importance of maintaining good oral hygiene during the period of chemotherapy cannot be overstressed. Frequently, the patient may need professional help to achieve optimal oral hygiene.

It is, if possible, desirable to manage the most acute oral problems prior to the start of chemotherapy, as for patients subjected to radiotherapy. However, this is often impossible since chemotherapy is initiated rather quickly after diagnosis. Management of oral health is then scheduled to be performed just before the beginning of the second or third cycle of chemotherapy. It is important to obtain a current blood count before any invasive dental treatment, to prevent development of infections, and any undesirable postoperative bleeding. A leukocyte count of $<0.5 \times 10^9/l$ (neutropenia) is considered to represent a high risk of infection. A count of $0.5\text{--}1.0 \times 10^9/l$ should be accompanied by antibiotic treatment for 7–10 days postoperatively, whereas a leukocyte count of $>1.0 \times 10^9/l$ only should be followed by a single dose of antibiotics prior to any kind of surgery or other invasive dental treatment, i.e. scaling or endodontics. Extractions and endodontic treatment should be performed at the latest 10 days before an expected leukocyte count of less than $0.5 \times 10^9/l$.

Mucositis normally develops after 5–10 days of chemotherapy. At later stages, ulcers can develop. The ulcers can be infected secondarily with bacteria, viruses or fungi. They can also be very painful, resulting in nutritional problems.

Emotional well-being

For most patients, the term cancer is equivalent to a death sentence. It is of great importance to thoroughly inform each patient as an individual as well as on a general basis with regard to the treatment opportunities that are available, the prognosis of the desired treatment, and expected side-effects. It is also of great importance to stress the fact that many patients today can be completely cured from a malignant disease. All information should be given to both the patient and to relatives. Often, reinformation is needed.

Professional psychological care is frequently indicated in order to assist the patient through the life crises that a cancer diagnosis implies. Psychological assistance can, to some extent, be of value for a relatively long period of time after termination of oncological treatment.

Follow-up

It is recommended that patients are followed up on completion of the cancer therapy, irrespective of treatment given to the patient. Follow-up of the patient is usually performed by all treatment disci-

plines involved. One reason is to discover early any signs of cancer recurrences. The earlier a recurrence is observed the better is the prognosis. Early after completion of the oncological treatment, follow-ups are more frequent, but with increased time after the treatment, and if there is no sign of recurrence, the period between each follow-up visit is extended. The patient should be followed for life, but due to mostly socioeconomic factors, follow-ups are terminated after 5 years.

From an odontological point of view, it is important to frequently evaluate the oral as well as the dental health with regards to development of carious lesions, periodontal problems, and early signs of development of both soft tissue necrosis and osteoradionecrosis. Professional dental cleaning can be of great value for a long time after termination of the oncological treatment.

Management of postradiation conditions

As mentioned, a number of conditions can be observed in patients after completion of radiation therapy. Some of these effects can be seen relatively early after radiotherapy, whereas some can occur as late as up to 10 years after. It is not possible to forecast when, or sometimes even if, osteoradionecrosis or soft tissue necrosis will occur.

To reduce the xerostomia the patient should be recommended frequent intake of small amounts of water. Today, there are also a number of saliva replacement products, artificial saliva, and saliva-stimulatory products available on the market, which have many positive effects on oral well-being. The use of such products can also be of benefit for taste. Life-long use of additional sodium fluoride products, i.e. daily rinsing, should be recommended in order to prevent rapid development of dental caries. Frequent and scheduled visits to a general dentist and/or a dental hygienist are desirable.

Fig. 35.6 A clinical view of a severe case of osteoradionecrosis in the anterior part of the mandible.

Fig. 35.7 Radiographical appearances of osteoradionecrosis. (a) At an early stage. (b) At an intermediate stage. (c) At a late and severe stage. In the late stage the mandible has fractured.

Reduced mouth-opening capacity is another late side-effect of irradiation. Different training programs are available to prevent early development of this condition. Sometimes it can be of benefit to begin the training already prior to radiation, and continue it as soon as possible after termination of treatment. A very strict and frequent use of these training programs is desirable since the effect is quickly reduced and even eliminated if they are not followed. Today, a number of mouth-training devices are also available on the market.

Soft tissue and bone necrosis (osteoradionecrosis) are the side-effects that usually develop last (Figs 35.6 and 35.7). It is not possible to predict which patient is at risk for development of these conditions, though they rarely occur in tissues subjected to less than 55Gy of radiation. To prevent the development of these conditions it is of benefit to treat dental problems immediately and conservatively, i.e. regular visits to a general dentist to prevent development of both periodontal disease and dental caries. Dental extractions should be avoided as long as possible. Instead, endodontic treatment should be the treatment of choice when apical periodontitis has developed. If extraction is the only alternative, it should be performed surgically with the aim of covering the

area with soft tissue. Systemic use of antibiotics for 7–10 days is recommended.

When and if osteoradionecrosis has developed, it is important to maintain good dental hygiene, to prevent development of infections in the affected area.

Some alternatives are available to reduce the speed of development, although controversy remains. Hyperbaric oxygen treatment has been used to reduce the development of, and also to treat, osteoradionecrosis.⁵ In later stages of osteoradionecrosis it may be necessary to carry out surgical resection, with or without adjunctive hyperbaric oxygen. Microvascular reconstruction, using free flap technology, after surgical resection of the affected area, is today a relatively common treatment in order to restore both function and esthetics in this group of patients.

Chapter 36

Salivary Gland Disorders

Mark McGurk and Jeremy Sherman

This chapter is devoted to salivary gland disease, which is classified by its clinical presentation as:

- discrete single or multiple masses within a gland;
- diffuse enlargement of a gland;
- intermittent swelling of a gland (obstruction);
- bilateral swelling of glands;
- infection;
- xerostomia (dry mouth);
- drooling.

Emphasis is given to less invasive surgical procedures including endoscopic and non-invasive management of salivary calculi and more localized surgery for many types of salivary gland tumors.

Diseases of the salivary glands are relatively uncommon but because of the glands' function and position within the complex anatomy of the head and neck they have particular interest for surgeons. Three main disease entities are encountered on a regular basis, namely obstructive disease, salivary tumors, and inflammatory disorders (mainly Sjögren's syndrome), in order of frequency. The remainder are vanishingly scarce and cannot be covered comprehensively in a single chapter on salivary gland disorders.

In terms of development, the subject has remained relatively static throughout the 20th century as disorders of the salivary glands are infrequent. Thus experience has been dissipated over multiple specialties. This resulting dilution of practical knowledge meant that dogma went unchallenged and was recycled from one textbook to another. Now a revolution is under-

way in salivary disease management. Many of the principles on which treatment has been based are being challenged. This chapter aims to highlight these new developments within our area of clinical practice.

Differential diagnosis

Introduction

Salivary gland disorders present to clinicians in several different ways as listed in Table 36.1. These will be used as the template to classify salivary disease as an alternative to the traditional pathological classification (inflammatory, neoplastic, autoimmune, etc.). Table 36.2 lists pathological entities by clinical classification.

Table 36.1 Categorization of salivary pathology by clinical presentation.

Discrete single or multiple masses within a gland
Diffuse enlargement of a gland
Intermittent swelling of gland (obstruction)
Bilateral swelling of glands
Infections
Xerostomia (dry mouth)
Drooling

Table 36.2 Pathological entities by clinical classification.**Discrete single or multiple masses within a salivary gland****Granulomas and chronic infections**

Tuberculosis (TB)

 Graft-versus-host disease
 Non-autoimmune salivary gland disease
 Amyloid
 Sarcoidosis
 Churg–Strauss syndrome
 Metabolic salivary gland disease
 Endocrine
 Liver, gastrointestinal disease and malnutrition
 Bulimia nervosa
 Cystic fibrosis
 Miscellaneous

The full spectrum of salivary gland disease can be seen across all age groups but the frequency of each entity tends to vary with age. In childhood developmental conditions predominate (hemangiomas and lymphangiomas), in middle age the emphasis is on inflammatory/obstructive disorders and to a minor extent neoplasia, whereas in the elderly neoplasia needs to be excluded. Swellings that occur in either the tail of the parotid or in the submandibular triangle fall within the differential diagnosis of a lump in the neck.

Investigations

Salivary glands are easily accessible and open to a wide range of investigative techniques. The first-line investigation is usually high-resolution B-mode ultrasonography. It is now readily available and is becoming part of the basic equipment in the surgical office. It can reliably distinguish between intra- and extraglandular masses, accurately recognize calculi/strictures and can demonstrate changes within the parenchyma. Doppler flow studies can identify vascular pathology. Conventional plain radiographs are virtually obsolete except for the ability to show small (<2 mm diameter) calculi within the ductal orifice. Traditional sialograms are still useful when investigating stones and evaluating strictures, prior to sialendoscopy (see Obstructive disease, later), and have not been superseded by magnetic resonance imaging (MRI) sialograms, except in expense. Salivary masses deserve more detailed evaluation by MRI (with modest superiority over computed tomography (CT)) and recent developments such as diffusion-weighted and dynamic contrast-enhanced MRI may, in the future, permit routine visualization of the facial nerve, although at present this is still a research tool. Salivary gland scintiscans assess glandular function.

The second most useful investigation to the salivary clinician is fine-needle aspiration cytology (FNAC). The prospect of a reliable tap can be improved by ultrasound- or CT-guided aspiration, especially if an experienced cytologist or cytology technician is in attendance. A competent cytological service should be able to distinguish between benign and malignant disease in over 85% of cases.^{1–3} A correct histological diagnosis is more problematic and results cannot be relied on but the technique has particular value when a neoplasm is not suspected and if this is confirmed surgery can be avoided.⁴

Although frequently overlooked, FNAC is a useful way to sample the discrete intraoral mass, as is a punch biopsy (dermatological punch). FNAC has particular relevance in managing the submandibular mass because of the high risk of malignant diseases at this site. A Tru-cut core biopsy may be useful if lymphoma is suspected, and may thus avoid the need for surgery.

Diagnostic message

Disease risk influenced by age
 Mass in the tail of the parotid and submandibular gland falls within the differential diagnosis of a lump in the neck
 FNAC/core biopsy can be used to sample intraoral masses

The discrete salivary mass

The overbearing responsibility in the presence of a discrete lump is to confirm or refute the presence of a neoplastic lesion. Particularly with granulomatous disease, the risk is to mistake the indurated tuberculous mass for an indolent cancer.

Granulomas and chronic infections**Tuberculosis**

Salivary tuberculosis usually manifests as a slowly enlarging painless mass that can masquerade as a neoplasm in about 3% of cases.⁵⁻⁷ In many instances the chest radiograph is normal and there is no lymphadenopathy. Diagnosis requires a high threshold of suspicion (Fig. 36.1) and knowledge of risk factors

Fig. 36.1 Persistent granuloma in an individual recently arrived from Malaysia which proved to be tuberculosis.

(ethnic group, recent travel abroad to endemic countries, old age, malnourished, alcoholism/drug addiction, and HIV infection). The saliva contains few if any bacilli⁸ and diagnosis is usually secured by FNAC or core biopsy. Mantoux or purified protein derivative (PPD) testing is often unhelpful due to previous BCG immunization.⁷ Anti-tuberculosis chemotherapy is the treatment of choice.^{9,10}

Non-tuberculous mycobacterial infection

This condition can be indistinguishable from the traditional tuberculous lesion and typically *Mycobacterium avium intracellulare*, *M. chelonae*, *M. malmoense*, *M. bovis*, and *M. scrofulaceum* organisms may be isolated.^{10,11} Polymerase chain reaction (PCR) assay facilitates rapid identification. Antibiotic therapy (clarithromycin, possibly long term) is the treatment of choice.¹²⁻¹⁵

Cat scratch disease

This self-limiting zoonosis is caused by *Bartonella henselae*.¹⁶ It may present as single or multiple enlarged preauricular facial or upper cervical lymph nodes. Parotid involvement occurs in about 3% of cases.¹⁷ It follows direct feline contact and a small papule forms at the site of inoculation accompanied by low-grade fever and general malaise. Rarely, conjunctivitis, encephalopathy, and cranial nerve palsies may arise. Diagnosis is usually through specialist hematological tests (Hangar-Rose antigen) or nodal biopsy. Treatment is largely symptomatic and co-trimoxazole or penicillin may stop ugly sinus formation.¹⁶⁻¹⁸

Actinomycosis

Salivary gland involvement is rare;¹⁷ anaerobic culture or histopathological analysis of a biopsy specimen clinches the diagnosis. Long-term penicillin therapy achieves a cure.

Hydatid disease

Echinococcus granulosus is rare and limited to rural and sheep-rearing areas.^{9,19} The parotid gland is implicated in 1-19/1000 patients with this disease⁹ and in appropriate circumstances the combination of eosinophilia, a raised erythrocyte sedimentation rate (ESR) (>50 mm/h), and a positive Weinberg complement fixation test establishes the diagnosis.⁹ Treatment is surgical removal but without rupture.²⁰⁻²⁴

Syphilis

Syphilitic parotitis is mainly of historical interest and is confirmed by serology.

Inflammatory conditions

Kim-Kimura's disease

The disease typically presents in young oriental males (male to female ratio 1:5) occurring at any age,^{25–27} as either single or multiple slowly enlarging indolent subcutaneous or salivary nodules²⁶ with or without regional lymph node involvement.^{25,28,29} The condition is endemic in the Far East and has an unknown aetiology.^{30–32}

Histologically the picture is one of lymphoid follicle formation with marked eosinophils and surgery is the only effective treatment.

Castleman's disease

This uncommon disease presents typically as a solitary, painless, slow-growing mediastinal mass (86%);^{33,34} only 2% involve the intraglandular or paraglandular parotid lymph nodes^{35–42} in adults between 15 and 35 years of age.³⁴ The condition is associated with fever and immunological disturbances⁴³ (including HIV,⁴⁴ myasthenia gravis,⁴⁵ severe erosive lichen planus,⁴⁶ pemphigus vulgaris,⁴⁷ monoclonal hypergammaglobulinemia, hypoalbuminemia, refractory anemia,^{34,48–50} or thrombocytopenic purpura.⁵¹ Histology reveals lymph node hyperplasia, either a hyaline vascular form (80%) or plasma-filled type.^{34,52} Treatment is complete surgical excision^{42,53} but supported by radiotherapy and chemotherapy where appropriate.⁵⁰

Kuttner tumor

This is a rare form of chronic sclerosing sialadenitis^{54–56} of the submandibular gland. It is an ill defined and probably not a homogeneous entity.⁵⁶ Diagnosis is difficult and usually relies on excision biopsy.

Inflammatory pseudotumor

This is a rare but real entity. It consists of an autoimmune inflammatory mass with features that mimic cancer in various organs (e.g. especially lung and liver).^{57–62} Presentation includes a unilateral painless induration, cicatrization, trismus, with neurological involvement but without lymphadenopathy.⁵⁸ Diagnosis is by open biopsy and excision may not be practical. It can be controlled by high-dose steroids.

Cystic lesions

Simple cysts (mucocele/ranula)

These are easily diagnosed by their bluish spherical appearance (Fig. 36.2) or aspiration (no risk of infection). The majority (>90%) are extravasation mucoceles.^{63–64} Ranulae arise from the lesser sublingual gland, and the plunging ranula^{65–68} has the distinc-

tion of running into the submandibular space creating a diagnostic problem. Careful ultrasound evaluation will demonstrate a dehiscence in the mylohyoid muscle and provide an aspirate of saliva. As ranulae originate from the lesser sublingual gland⁶⁶ treatment consists of sublingual gland removal. The ranula sac can be left *in situ* (after aspiration of saliva).⁶⁶

HIV-associated salivary gland disease

Human immunodeficiency virus 1-associated salivary gland disease (HIV-SGD) is a term that has been used to define enlargement of one or more major salivary glands (60% bilateral^{69–75}) and/or xerostomia in HIV-1 infected patients.^{69,70} Solitary gland involvement is rare (2%). About 5% of cases develop cosmetically debilitating bilateral parotid cystic enlargement (Fig. 36.3).^{76–79} Symptoms and ultrasound images may mimic Sjögren's syndrome.^{69,80–84} Surgical treatment has been replaced by highly active antiretroviral therapy (HAART). There may be an increased risk of associated salivary gland lymphoma.^{79,80}

Dermoid cysts

Occasionally, a dermoid cyst occurs in the parotid or floor of mouth. They are diagnosed by clinical features and FNAC.⁸⁵

Congenital duct cysts

Congenital duct cysts are retention cysts (Fig. 36.4) of the parotid gland and are rare. Treatment is conser-

Fig. 36.2 Extravasation cysts on (a) floor of mouth (ranula) and (b) the lip (mucocele).

Fig. 36.3 HIV-SGD: multiple cysts involving both parotid and submandibular glands.

vative.^{64,86} Repeated aspirations yield amylase content >15 000 IU/ml, confirming the diagnosis.

Polycystic disease of the parotid gland

This entity is very rare; only eight cases have been reported, affecting only females.^{87–92} The cystic changes usually do not involve the main parotid duct and are demonstrable by sialography or ultrasound. Treatment is conservative.⁸⁹

The intermittently swollen gland

The obstructed gland (see Obstructive disease)

Mucus plugs

The development of thick gelatinous saliva is probably a regular occurrence and goes undetected in normal pliable ducts. Plugs only become symptomatic in the presence of an obstruction. In most cases there is a concurrent stricture. The symptoms are subtly different to mealtime syndrome with nothing found during ultrasonography. Plugs form with stagnation, therefore symptoms occur on waking and after periods of dehydration. Sialogogues and massage are normally sufficient to control symptoms but irrigation via sialendoscopy plus balloon dilatation of the stricture is also an option.

Polyps

Pedunculated lesions arising from the duct lining may remain asymptomatic until picked up on sialendoscopy. Their significance is unknown.

Fig. 36.4 Left parotid duct cyst.

Foreign body impaction

This is a rare occurrence and many reports are anecdotal (e.g. grass seed, fish bones). In the context of salivary gland disorders it is not an important entity.^{93–95}

Pneumoparotid (trumpet blower's syndrome)

Air insufflation of the parotid is a real entity. The parotid duct has a valve-like structure and a tight puctum that stops air passing into the duct. If these are incompetent then air and bacteria pass up the duct. This may be one of the mechanisms involved in "relapsing parotitis of childhood". Symptoms may coincide with playing wind instruments.⁹⁶

The diffusely enlarged gland

Infection (bacterial and viral)

Acute viral sialadenitis

Over a third of all pediatric salivary gland disorders are of an inflammatory nature, with either an obstructive or non-obstructive etiology.⁹⁷

There is a wide range of viral infections that can involve the salivary glands (Coxsackie A⁹⁸ and B3,¹⁰⁰ parainfluenza B,^{101–106} ECHO type 9,¹⁰⁷ and Epstein-Barr^{108–111}). The most common is mumps. It is caused by a highly infectious paramyxovirus with an incubation period of 2–3 weeks.^{112,113} The subject is infectious from 5 days prior and 10 days after the onset.^{113–116}

If the diagnosis is in doubt, the virus can be cultured from saliva^{113,115} or established from rising antibody titres (S-antigen followed by V-antigen). The V-antibody confers life-long immunity.^{116–120}

In adults, the condition may be more severe and complicated by orchitis or oophoritis and varying degrees of meningoencephalitis are relatively common (25%). In rare instances, occurrence may be unilateral.

Juvenile recurrent parotitis

This is another real clinical entity! Juvenile recurrent parotitis (JRP) is a unique non-obstructive, non-suppurative, usually unilateral variant of sialadenitis and represents the second most common parotid disorder amongst young children (Fig. 36.5). Traditionally it is considered a self-limiting condition⁹⁶ but Maynard followed a cohort of children into adulthood and reported continual problems in approximately 30–40% of cases.¹⁷

It is probable there is more than one etiology (see Table 36.3). Incompetent parotid ducts, juvenile Sjögren's syndrome, lymphoma, HIV-SGD amongst

Fig. 36.5 Young boy with a history of recurrent parotid infection that induced systemic symptoms. Parotid gland wash-out (yearly) and long-term antibiotics contained symptoms.

others, congenital ductal malformations, genetic factors, bacterial or viral infection, allergy or autoimmune congenital immunoglobulin deficiency have also been postulated.^{121,122} In Kaban's series of eight patients, 62 episodes of infection were recorded (range 8 weeks to 11 years). A single patient experienced 18 acute attacks.¹²³ The symptom-free interval may be increased following duct lavage.^{124–125} Intermittent bilateral ductal lavage (normal saline, 100mg hydrocortisone and amoxicillin–clavulanic acid 25mg/kg via a sialendoscope) is becoming the treatment of choice.¹²¹

Bacterial sialadenitis

The condition is uncommon nowadays and when it does occur it is invariably related to salivary calculi^{126,127} and/or a predisposing medical condition (immune suppression).^{129–132} It may also arise as an acute exacerbation of chronic sialadenitis (Fig. 36.6). The author's recommended protocol for management is listed in Table 36.4.

Table 36.3 Local or systemic predisposing factors for acute suppurative sialadenitis in childhood.¹²²

Fever and/or dehydration secondary to an upper respiratory tract infection, systemic viral illness or acute glomerulonephritis
Immunosuppression secondary to congenital immunoglobulin deficiency or chemotherapy for acute leukemia
Failure to thrive or respiratory distress syndrome in premature or newborn infants
Previous trauma or mumps involving the parotid gland

Fig. 36.6 Acute parotitis as a result of a retained stone.

Historically, parotitis was traditionally associated with postsurgical patients, who were often dehydrated, and was frequently the final event of a debilitating illness. Parotitis is uncommon today due to greatly improved standards of perioperative care, especially with respect to maintenance of hydration. Parotitis in the otherwise well patient is now nearly always secondary to a salivary stone and chronic infection can follow radiotherapy. First-line treatment consists of antibiotics targeted at staphylococci and streptococci.^{130,133} Other less commonly implicated microorganisms are listed in Table 36.5.¹³⁴ Surgical intervention (drainage) is seldom required apart from stone removal.

Chronic/subacute sialadenitis

Chronic sialadenitis is usually unilateral, recurrent, and secondary to an underlying obstruction (stone or foreign body).¹²⁶ Approximately 2% of patients with Sjögren's syndrome are affected each year.^{133,135–137} The duct orifice appears inflamed with an accompanying purulent, salty tasting discharge. Maynard demonstrated the sequential architectural changes by parotid sialography (Table 36.6).¹³⁸ Maynard also demonstrated that the salivary secretion rate is significantly reduced in patients with recurrent parotid

infection. Interestingly, an apparently normal contralateral gland will exhibit a similar reduction in flow rate in cases of recurrent subacute parotitis, when compared to controls.¹³⁸

Autoimmune salivary disease**Benign lymphoepithelial lesions**

Mikulicz (1888) described painless enlargement of the major salivary glands and lacrimal glands which in hindsight was probably a MALT lymphoma. Benign lymphoepithelial lesions (BLL is an umbrella term)¹³⁹ describes focal collection of lymphocytes which gradually form follicles seemingly identical to mucosa-associated lymphoid tissue (MALT).^{140,141}

Sjögren's syndrome

Primary Sjögren's syndrome has the histological features accompanied by dry eyes and mouth; if accompanied by a connective tissue disorder (systemic lupus erythematosus (SLE), polyarteritis nodosa, CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), dermatomyositis, systemic sclerosis) or primary biliary cirrhosis, it is secondary Sjögren's.^{142–145} Other supposed symptom complexes have been identified (sialadenitis, nodal osteoarthritis and xerostomia, SOX).¹⁴⁶ Sjögren's syndrome subjects have a 44 times increased risk of developing lymphoma¹⁴⁷ with an incidence of 5–10% of cases.^{148–150} It is estimated that 1% of the

adult population (mean age 50 years: female predominance of 10:1) have Sjögren's syndrome.^{151,152}

The European criteria for establishing Sjögren's syndrome are shown in Table 36.7.¹⁵⁴

Salivary mucosa-associated lymphoid tissue (MALT) lymphomas

These tumors are uncommon (about 1 case per million population per annum) and were first recognized by Isaacson and Wright in 1983.¹⁵⁴ They are the most common lymphoma to affect salivary tissue and the third most common of the non-Hodgkin lymphomas. In the head and neck most occur in the parotid (parotid 88%, submandibular gland 3%, minor glands 9%). Females represent 80% of cases, ranging in age from 14–72 years. It is difficult to decipher when a swollen Sjögren's gland slips into a MALT lymphoma.^{155,157,158} Suspicious features are engorged painful parotid glands (Fig. 36.7). This symptom is usually erroneously interpreted as subacute sialoadenitis but no pus

**Fig. 36.7** Long-standing parotid swelling (10 years plus) initially thought to be due to sarcoid. Tail of parotid biopsy confirmed MALT lymphoma.

Table 36.7 European criteria for the classification of Sjögren's syndrome (after Vitali *et al.*¹⁵³).**I Ocular symptoms**

A positive response to at least one of the three selected questions:

- Have you had daily, persistent, troublesome dry eyes for more than 3 months?
- Do you have a recurrent sensation of sand and gravel in the eyes?
- Do you use tear substitutes more than three times a day?

II Oral symptoms

A positive response to at least one of three selected questions:

- Have you had a daily feeling of dry mouth for more than 3 months?
- Have you had recurrently or persistently swollen salivary glands as an adult?
- Do you frequently drink liquids to aid in swallowing dry food?

III Ocular signs

Objective evidence of ocular involvement defined as a positive result in at least one of the following two tests:

- Schirmer's I test (<5 mm in 5 minutes)
- Rose Bengal score (>4 according to van Bijsterveld's scoring system)

IV Histopathology

A focus score >1 in a minor salivary gland biopsy. A focus is defined as an agglomerate of at least 50 mononuclear cells; the focus score is defined as the number of foci in 4 mm³ of glandular tissue

V Salivary gland involvement

Objective evidence of salivary gland involvement defined by a positive result in at least one of the following three diagnostic tests:

- Salivary scintigraphy
- Parotid sialography
- Unstimulated salivary flow (<1.5 ml in 15 minutes)*

VI Auto-antibodies: presence in the serum of the following antibodies:

- Antibodies to Ro(SS-A) or La(SS-B) antigens or both

Rules for classification

In patients without any potentially associated disease the presence of any four of the six items is indicative of primary Sjögren's syndrome but must include positive result from factors IV or VI. In patients with a potentially associated disease (e.g. another connective tissue disease), items I or II plus any two from among items III, IV, V are indicative of secondary Sjögren's syndrome. But if such a patient is positive for ENA antibody then this is a specific marker for primary Sjögren's and even if there is an associated CT disease the patient is classified as primary Sjögren's

Exclusion criteria

Pre-existing lymphoma, acquired immunodeficiency disease (AIDS), sarcoidosis, graft-versus-host disease, sialoadenosis. Use of antidepressant and antihypertensive drugs, neuroleptics, parasympatholytic drugs

* As it has been demonstrated that this test may be reduced in normal subjects older than 60 years, it should be excluded from the criteria or not considered indicative for a diagnosis of Sjögren's syndrome in elderly subjects.

can be milked from the gland. Unexpected vascular events (pulmonary emboli, thrombosis, leg ulcers, and anemia) are also suggestive of lymphoma. Ultrasound examination (multiple cyst formation) with the appropriate history is almost pathognomonic. A definitive diagnosis is dependent on histological examination following Tru-cut core biopsy and an assessment of clonality. This indolent disease can change into a high-grade lymphoma with about 8% succumbing to their disease.¹⁵⁶

Wegener's granulomatosis

This is an immunological disorder and salivary gland enlargement does not occur in isolation but rather with nasal, pulmonary, and renal system problems.^{159–162} The diagnosis is confirmed by circulating anti-neutrophil cytoplasmic autoantibody (ANCA)^{163–165} and biopsy.

Graft-versus-host disease

Xerostomia¹⁶⁶ and submucosal retention cysts¹⁶⁷ have been recorded during immunosuppressive therapy following bone marrow transplantation.

Non-autoimmune salivary gland disease**Amyloid**

Amyloidosis presenting as a salivary mass is exceedingly uncommon.^{168,169} It can be confirmed by biopsy.^{170,171}

Sarcoidosis

Sarcoidosis is a disease of unknown etiology characterized by non-caseating granulomas. It is a systemic illness presenting with general malaise usually between 20 and 40 years of age.^{172–177} In 35% of cases there is either unilateral or bilateral diffuse parotid gland involvement;¹⁷² the disease is usually self-limiting.¹⁷⁸ A subgroup with Heerfordt's uveoparotid fever have a triad of uveitis, bilateral parotid swelling, and cranial nerve involvement. A positive Kveim test, a raised angiotensin converting enzyme (ACE), and a positive gallium scan^{179–180} are indicative of sarcoidosis, which is confirmed through biopsy.¹⁸¹

Churg-Strauss syndrome

The syndrome consists of the triad of allergic rhinitis, asthma, and hypereosinophilia in association with a systemic vasculitis (involving small and medium-sized arteries).¹⁸² It is unmistakably a systemic disorder and not isolated to the salivary glands. Symptoms are controlled by intermittent steroids, but excision of the gland may ultimately be required.

Metabolic salivary gland disease

Endocrine and gastrointestinal disease

This complex lacks scientific scrutiny. Most patients are obese. It is possible in these individuals, that fat is directed to the parotids as well as other select areas of the body (Fig. 36.8). Not surprisingly it has been linked to diabetes mellitus,^{183–186} acromegaly, diabetes insipidus, thyroid disorders,^{187–190} gonad dysfunction,¹⁹¹ and gastrointestinal^{192–196} and liver disease.^{197–199}

Bulimia nervosa

Up to 50% of patients with bulimia nervosa have parotid gland hypertrophy.^{200–204} This is thought to be a physiological response to repeated hypochloremic alkalosis.²⁰² Affected females are painfully thin and the glands stand proud (Fig. 36.9). The consultation is usually for cosmetic reasons.

Cystic fibrosis

In cystic fibrosis, mucus plugging may cause chronic obstruction, resulting in interstitial fibrosis.^{205–207} This is another vanishingly rare problem.

Miscellaneous

Excessive starch ingestion^{208,209} and other sporadic causes of drug-induced diffuse gland enlargement,

xerostomia or ptyalism are listed in Tables 36.8–36.10.^{210–212}

Obstructive salivary gland disease

Introduction

In the last decade a revolution has occurred in the management of obstructive salivary gland disease with the introduction of minimally invasive techniques. Stone clearance is achieved in 80% of cases and gland removal reduced from 100% to 3%.²¹³ Historically the rationale for gland removal was that a calculus induces irreversible parenchyma damage which in turn leads to chronic sialadenitis. However for those stones that migrate to the punctum rather than remain in the proximal duct, the argument is overlooked for they are released by a simple incision. The only reasonable explanation is that the policy has developed mainly around ease of surgery and not risk of subsequent sialoadenitis. There is increasing evidence that salivary glands recover function following stone removal and remain asymptomatic.^{214–218} This is the foundation on which minimally invasive treatment is based.

Investigation

A history of repeated preprandial swelling (mealtime syndrome) is almost pathognomonic of salivary gland obstruction. The exception is a salivary stricture. Stagnant saliva leads to mucus plugs which become impacted in the stricture so symptoms typically

follow a period of reduced gland activity such as sleep. The obstruction is frequently released after massage which in turn is followed by a gush of salty saliva. There is a number of investigations that complement clinical assessment (Table 36.11).

Ultrasonography

The main salivary glands (parotid, submandibular, and sublingual) are assessable to sonographic evaluation (frequencies of 7.5–13.5 MHz) which is available in most health care systems. A stone >2 mm diameter is reliably detected as an echo opaque reflection with distinct distal shadowing (Fig. 36.10). A dilated duct proximal to the echo clinches the diagnosis and dilation without an echo suggests the stricture. The

parenchyma can also be assessed: a normal salivary gland has a diffuse homogeneous appearance and one with chronic inflammation has a coarse image due to cyst formation and fibrosis.

Consequently ultrasound imaging can be used to monitor recovery following treatment and portable ultrasound machines are an invaluable adjunct to current clinical practice.

Sialography

A sialogram is also a valuable investigation (Fig. 36.11) for it can identify the size, position, and mobility of a stone (the latter has an impact on the choice of treatment) but its main advantage over ultrasound is its ability to provide information on the number and shape of strictures (single, discrete, diffuse, multiple). A sialogram should be avoided when the gland is clinically infected or the patient is allergic to iodine. An air bubble introduced inadvertently during sialography can mimic a salivary stone.

Plain film radiography

The average submandibular duct stone can be easily demonstrated by a mandibular true lower occlusal view, while large hilar stones can be seen on the panoramic or an oblique lateral radiograph. The only real

Fig. 36.10 Ultrasound scan demonstrating a 4.9mm calculus at the hilum of the submandibular gland.

Fig. 36.11 Submandibular sialogram showing calculi. The fact that the duct is dilated along its length suggests the stones are mobile and suitable for basket retrieval.

use of plain radiography is to detect small stones (<2mm) resident in the distal portion of the submandibular or parotid ducts; it is more sensitive if the recommended radiation exposure is reduced for these views. However, this imaging modality has limited application in obstructive disease.

CT and MRI scans

CT and particularly MRI imaging can be used, in the absence of simpler modalities, to demonstrate stones and chronic inflammation²¹⁹ but they should really be reserved for evaluating salivary tumors. MRI has limitations as it is sometimes difficult to distinguish between bone and calcified tissue which, together with blood vessels, appear black. Consequently calcified bodies such as small stones may be over-

looked.^{219,220} The use of 3D rapid spin-echo sequences has improved the detection of stones²²¹ (91%) and strictures (100%) but CT scans frequently produce artefacts and are prone to produce false-positive results. Both modalities can be used with sialography.

One new intriguing application of this technology is the computer manipulation of MRI data to provide virtual endoscopic pictures of the salivary duct.^{222,223} The disadvantages of MRI are its cost, restricted access, and inability to apply it to patients with pacemakers or ferromagnetic implants. In practice there are simpler, easier, and less expensive methods of detecting an obstruction in the parotid duct.

Sialolithiasis

Demographics

The largest published series of salivary stones ($n = 4691$) shows a remarkable similarity in demographic data between five independent salivary units (Table 36.12).²¹³

There is usually a significant delay (greater in the submandibular gland) between the initiation of symptoms and seeking a medical opinion consultation (parotid 4.8 years, submandibular gland 5.4 years) and this correlates with submandibular stones being larger than parotid calculi.²²⁴ The medical consultation is normally triggered by the advent of acute or subacute sialadenitis which signals a move to chronic sialadenitis.

The analysis of hospital admission data in the British NHS system established a hospital admission rate for sialoadentitis and sialolethiasis of 59 cases per million annually. Calculated over a lifetime (70 years) this gives a prevalence of 0.45% for acute symptomatic disease.²²⁵ The anatomical distribution of calculi

Table 36.12 Demographic data relating to $n = 4691$ salivary calculi treated at five centers specializing in minimally invasive therapy.²¹³

Parameter	Erlangen	Israel	London	Milan	Paris

Mean duration symptoms parotid (month)	37	24	44	50	34
Mean duration symptom submandibular	23	18	49	43	27

Fig. 36.12 Site distribution of salivary calculi in the parotid and submandibular glands.

shows that 63–94% occur in the submandibular gland and the remainder occur in the parotid gland (Fig. 36.12). The wide variation is due to the reluctance of patients with parotid stones to submit to surgery. Consequently a reservoir of patients with parotid stones can build up within pockets of the community. Multiple stones occur in 7% of parotid and 13% of submandibular glands but stone formation in more than one salivary gland is uncommon (<1%).²²⁵

Pathogenesis of salivary stones

The steps by which salivary gland stones develop have not been fully elucidated. It is probable that this process is multifaceted with one important item being the anatomical configuration of the salivary ducts. Both duct systems have kinks (90% bend) and stones seem to congregate at these kinks (Fig. 36.13).

It is hypothesized that a calculus forms from a nidus of debris. Calcium-binding proteins are present in both the salivary and the renal systems and a deficit of crystallization inhibitors has been proposed as a cause of kidney stone formation.²²⁶ No such association has been demonstrated in the salivary glands nor is water hardness relevant.²²⁷

Harrison has shown that the salivary glands produce a continual stream of microcalculi²²⁸ which are a protective mechanism, whereby calcium ions neutralize active phospholipids exposed within dam-

aged cells.²²⁹ Harrison holds that the microcalculi cause obstruction followed by focal atrophy which leads to ascending infection and propagation of the cycle. A more likely scenario is that microcalculi are continually washed down the duct system and through a combination of chance and transient local conditions (inflammation, mucus plug, stagnation) the debris comes to lodge at a kink in the duct and subsequently acts as a nidus for calcium precipitation. This would account for the orderly precipitation depicted by calcium rings with a stone (Fig. 36.14).²³⁰

The submandibular stone has a significant inorganic component (80%) and tends to be radiopaque (94%) whereas the parotid sialolith is formed of 50% organic material and 43% are radiopaque.²³²

Pathogenesis of salivary strictures

The origin of salivary strictures is unclear. An analysis of over 1300 consecutive sialograms undertaken for obstructive symptoms²³³ demonstrated that approximately 25% of symptoms were due to stricture and the vast majority of these strictures occurred in the parotid gland (Table 36.13). Strictures can be pinpoint, multiple (giving a sausage-like appearance) or diffuse along the length of the duct (Fig. 36.15).

There is no apparent relationship to autoimmune diseases but strictures do occur following repeat treatment with radio iodine. The sialoendoscopic appearance shows circular bands of pale scar tissue reminiscent of tracheal rings, but, without understanding the pathogenesis, therapeutic intervention remains empirical. Why most strictures occur in the parotid gland remains a mystery.

Fig. 36.13 Long cone-beam CT sialogram demonstrating the parotid duct system.

Fig. 36.14 Micrograph of salivary calculus showing rings of calcium precipitation.

Table 36.13 Cause of symptoms in 1362 consecutive sialograms undertaken for obstructive symptoms. In 485 the duct was normal and in 877 there was evidence of obstruction (stones 642, strictures 198, plugs 37).²³³

	% of total	Parotid	Submandibular

Modern management of salivary calculi

The advent of minimally invasive salivary therapy was ushered in by innovations in the management of renal calculi. A salivary extracorporeal lithotripter (ECL) became commercially available (Storz Minilith: Storz Medical, Kreuzlingen, Switzerland) in the mid-1990s followed in 2000 by first-generation microendoscopes (Fig. 36.16), which then raised the possibility of intracorporeal lithotripsy (ICL). This proved a false dawn, for the salivary microenviron-

ment could not withstand the energy used in ICL without stricture formation.

Rationale of management

The armamentarium available for minimally invasive therapy includes an ECL (Storz Minilith), salivary endoscopes, microballoons, and an array of wire baskets and microforceps. These instruments should be used in combination and treatment is governed by stone size. Mobile stones <5 mm diameter are amenable to retrieval by basket, forceps or balloon under either radiological or endoscope control.²³⁴ In practice the basket is the easiest method of stone retrieval.

Stones >5 mm or fixed to the duct wall require alternative techniques. ECL is not very effective in eliminating submandibular stones (~30% stone clearance) when compared to the parotid (60%).²³⁵ Consequently large (>5 mm) or fixed submandibular stones are retrieved by endoscope-assisted surgery whereas those in the parotid (6–10 mm) are targeted by ECL. Large parotid stones (>10 mm) do not respond to ECL and similarly have to be removed by endoscope-assisted surgery (Fig. 36.17).

Intervention sialography

The technique commences with a sialogram. The salivary ducts have pressure sensors within their walls and to avoid discomfort the duct should be washed with 1% lidocaine or articaine solution. A dormia basket is advanced under fluoroscopic control until it passes the stone. The basket is then opened, rotated

Fig. 36.16 Examples of third generation endoscopes produced by Storz (a) and Polydiagnost (b, c). One is based on a reusable multichannel unit (Storz), the other on a disposable design that minimizes concerns with sterilization. Both are delicate instruments but possess greater flexibility than their predecessors.

	Parotid	SMG
Stone <5 mm	BASKET	BASKET
Stone >5 mm or fixed	Lithotripsy ↓ Failed lithotripsy (10%) ↓ Endoscope-assisted surgery	Endoscope-assisted surgery

Fig. 36.17 Flow diagram demonstrating the management protocol for salivary stones.

Fig. 36.18 Dormia basket retrieval of a SMG stone. Usually the punctum has to be incised to release the calculus.

and withdrawn to engage the calculus, which is withdrawn to the papilla and released (Fig. 36.18). If the selection criteria are used appropriately, the technique of basket retrieval is very effective in eliminating stones (Table 36.14).

In a series of patients treated at Guy's Hospital²³⁸ the clearance rate using current criteria was 86% (submandibular 87%, parotid 86%). Morbidity is minimal but there is a risk of inducing sialoadenitis; it is recommended that those with a history of infection should receive prophylactic antibiotics for 3 days.

Sialoendoscopy

Sialoendoscopy was initially used for diagnostic purposes but it is now routinely used therapeutically. The parotid duct is easy to cannulate (after dilation with a Nettleship dilator) whereas the submandibular punctum is usually incised and sutured open at the end of the procedure. The duct lumen is inflated with pulses of saline solution and the endoscope advanced under direct vision until the stone is identified. The basket is introduced either down the working channel of the endoscope or within the duct lumen parallel to the endoscope. As the basket is withdrawn it should be rotated to engage the stone and then both instruments retrieved together. A contraindication is a distal stenosis that prevents either entry of the

endoscope or retrieval of the stone past the stricture (once secured a stone cannot be released from a basket!). The reported success rate is 82% (Table 36.15).

Morbidity is minimal, but there is a small risk (2–8%) of strictures, subacute sialoadenitis 2–3%, ductal perforation 0–8.5%, basket block 0–6% or ranula formation 0.6–0.9%. Most of these complications are avoidable.

Lithotripsy

The shockwave generated by the ECL (Fig. 36.19) produces a compressive wave which passes through the calculus producing stress fractures. At the same time, the pressure wave induces vapor bubbles at the stone's surface. As the bubble collapses a jet of water strikes the stone drilling tiny holes in its surface.

It has become apparent that the chance of stone clearance is better in the parotid gland and with stones <8mm in diameter.²⁵¹ In 2006, Escudier (Table 36.16: unpublished data) undertook a prospective randomized study to establish factors that predicted for stone clearance. The only independent factor predicting for stone fracture was the size of stone.

The two factors that guide patient selection are the size and site of stone. The stone clearance rate in six published series with over 100 cases in each varied between 29 and 63%. The average clearance was 41% (Table 36.17).

Lithotripsy technique

The Storz sialolithotripter is designed for application in the outpatient setting. It is customary to leave about a week between treatments (due to a tender gland), but if necessary ECL can be undertaken on 2 or 3 consecutive days. The shockwaves are targeted with an ultrasound probe (Storz 7.5MHz) at a

frequency of 2 Hz (maximum pressure 36 MPa) usually over an hour (3000–5000 shocks per session) and with no requirement for analgesia.

If stone fragments persist after the initial course of three to four sessions, a second course can be under-

Fig. 36.19 Storz sialo-lithotripter.

taken. The outcome of treatment is usually assessed by ultrasound examination 4–6 months after completion of treatment and the long-term outcome is encouraging. In a 10-year review, patients rendered stone free did not develop recurrent disease (Table 36.18).

Gland-preserving surgery (endoscope-assisted stone retrieval)

Gland-preserving surgery is the treatment of choice for large or fixed submandibular stones and is usually reserved for those 10% of patients with parotid stones that remain symptomatic after ESWL. If no lithotripsy service is available large parotid stones can be reliably retrieved by this technique. The success rate for both techniques is in the region of 95% stone retrieval.

Table 36.17 Overall success rates for extracorporeal shock wave lithotripsy in 6 studies with 100 or more cases of salivary calculi. Stone clearance rate was 41% of cases treated. The differential clearance between parotid and submandibular gland was 53% vs 31%. Figures in parentheses are percentages.³¹⁶

Endoscope-assisted retrieval of submandibular calculi

This technique is reserved for stones in the middle or proximal portion of the submandibular gland. It can be performed in the outpatient or preferably a day-case setting. Two techniques have been developed which are similar except for one feature; the first lays open the duct (marsupialized to the floor of mouth) while the second leaves the duct intact (Fig. 36.20).^{257,238}

Palpable stones in the floor of mouth are ideally suited to this technique²⁵⁸ but repeat surgery is difficult and should be avoided. At the time of surgery an endoscope can be used to guide the surgeon and to check that no additional stones are present in the gland. The mean stone clearance rate is 92.1% with gland removal rate of 2.1% (Table 36.19). This represents a substantial change in clinical practice.

Endoscopic-assisted removal of parotid calculi

The first extra-oral parotid sialolithotomy without parotidectomy was described in 1991 by Baurmash

Fig. 36.20 Typical dissection of the floor of mouth to retrieve a stone from the hilum of the submandibular gland.

and Dechiara.²⁶⁷ The sialoendoscope helps to identify the duct for the light at the end of the endoscope acts as a beacon to direct the surgeon on to the stone (Fig. 36.21). The direct transcutaneous technique is applicable to large calculi situated on the anterior edge of the masseter muscle where the parotid duct is superficial. In contrast, proximal stones lie deep in the gland and it is here the endoscope shows its worth. The light at the end of the endoscope is used to mark the position of the stone and a preauricular skin flap is raised to expose the duct and stone. The buccal branch of the facial nerve runs parallel to the parotid cut and is easily visualized in the dissection. Prophylactic antibiotics are prescribed and a stent is optional. The data suggest^{268–270} that over 90% of

Fig. 36.21 The light at the end of the sialoendoscope is used as a guide to identify the duct and the position of the stone prior to surgical release.

stones can be retrieved successfully from the parotid (Table 36.20). An update of combined results (Guy's Dental Hospital, London, UK, the Barzilai Medical Centre, Ashkelon, Israel, and the Indiana University Medical Center, Indianapolis, USA) in 69 patients treated with the endoscopically-assisted open surgery and with a median follow-up of 25 months (range of 2–81 months) reported a stone clearance rate of 66/67 (98.5%). In general the complication rate is low (4.5%) and includes stricture, retained fragments, and scar formation.²⁶⁹ The downside is that the procedure requires hospital admission and treatment under general anesthesia.

Results of minimally invasive approach to salivary stones

In the last two decades, five centers have pioneered the use of minimally invasive treatment for the management of salivary calculi. One common theme is that no one technique was used in isolation. Treatment protocols have slowly been developed that are broadly similar in the five units. In the period 1990–2004, 5258 patients with 5993 salivary stones were seen in the five salivary centers.²¹³ Those patients who had stones released by a simple intraoral procedure or refused treatment ($n = 241$) were excluded as were those who had complete dental stenosis ($n = 11$), recurrent infective episodes or multiple stones neces-

sitating gland removal ($n = 63$) or they were lost following the initial assessment ($n = 11$). There was a learning curve and a number of patients were treated by minimally invasive techniques which have since been abandoned (intracorporeal lithotripsy). These cases ($n = 237$) were also excluded. The remaining 4691 consecutive cases treated by a minimally invasive approach were evaluated. The results are shown in Fig. 36.22.

Overall salivary stones were successfully removed in 3775/4691 (80.47%) of cases. Partial success (symptom-free but retained stone debris) was achieved in 782/4691 (16.67%) and these patients have not received further treatment or were lost to follow-up. Treatment failed in 134/4691 (2.8%) of cases resulting in salivary gland removal. Currently, if these patients were seen at a non-specialist unit, they would all have the gland removed.

Salivary gland tumors

New developments

- Warthin's tumor is a polyclonal lesion and not a neoplasm.
- Benign parotid tumor can be safely treated by minimal procedures much less than the traditional superficial parotidectomy.

Fig. 36.22 Results of minimally invasive therapy for salivary stones ($n = 4691$).²¹³

- Management of malignant salivary tumors should be governed mainly by stage rather than grade (+ histological type). The 4 cm rule is important.

General epidemiology

Until recently comprehensive population data for salivary gland tumors were incomplete, as benign neoplasms are not recorded by cancer registries and minor salivary gland cancers are coded with oral malignancy. There is supposedly a wide variation in the incidence between countries²⁷¹ with an increase reported in the USA from 6.3% of head and neck cancers in 1974 to 8.1% in 1999.²⁷² It is unclear whether this change is real or a feature of improved registration.

Clarity has arrived with a unique population-based study²⁷³ in a defined UK population of 604200 patients served by only two hospitals. The records for the period 1988–1997 were scrutinized and in total 517 patients with salivary gland tumors identified (Table 36.21).

It is notable that the benign:malignant ratio of tumors at each site did not conform to standard teaching. The proportion for the three main sites – parotid, submandibular, and minor salivary glands – was 6%, 34%, and 24% respectively. Previous data originated from large cancer institutes where a referral bias in favour of malignant disease may have distorted the data. The annual incidence for benign and malignant salivary tumors over the 10-year study period is shown in Table 36.22. The incidence of benign tumor was 7.2 and that for cancer 0.8 per 100 000. Data on malignant disease were comparable to National Cancer Registry returns, suggesting the remaining data are valid.

Etiology and risk factors

The causes of salivary gland tumors are largely unknown. A well established association exists with radiation which has been studied in the Japanese

Table 36.21 The proportions of benign and malignant salivary gland tumors in a defined UK population by anatomic site (1988–1997). The traditional 10:1:1 rule holds true for distribution of tumors between parotid, submandibular, and minor salivary glands. Figures in parentheses are percentages.

	Benign	Malignant	Total
Major salivary glands			
Parotid gland	397	26 (6)	423
Submandibular gland	35	12 (34)	47
Minor salivary glands	32	10 (24)	42
Sublingual gland	0	5 (100)	5
Total	464	53	517

Table 36.22 Annual incidence (per 100 000 population) of salivary gland neoplasms by site in defined UK population.

	Benign	Malignant
Major salivary glands		
Parotid gland	6.20	0.40
Submandibular gland	0.55	0.19
Minor salivary glands	32.00	0.16
Sublingual gland	0.00	0.08
Total	7.20	0.80

population surviving the atomic bomb.²⁷⁴ Assertions^{274–277} have been made that certain tumors (Hodgkin's disease, medulloblastoma, basal cell carcinoma) carry a secondary risk of salivary cancer. What these tumors have in common is that they all originated in the head and neck and were treated by radiation. The environmental factors that drive salivary glands towards neoplastic change remain largely unknown.

Investigation

A careful clinical history and examination are the foundation on which all subsequent investigations are based. As stated before, it is essential that lesions in the tail of the parotid or submandibular gland be

considered within the differential diagnosis of a lump in the neck. Tumors hidden in the retromandibular and submandibular area are more difficult to evaluate. The initial investigation of choice is ultrasonography which will immediately establish if the mass is intrinsic to the salivary gland or related to adjacent lymph nodes. The majority of cancers in the submandibular triangle are not of salivary gland origin and in sunny climates (Australia) the commonest cause of a malignant parotid lump is a metastasis from a tumor of the scalp.

Complex salivary gland masses that run deep to the mandible or are suspected of being malignant should be visualized by CT or preferably MRI scans. MRI offers superior soft tissue contrast and artifacts caused by dental fillings usually play a minor role on scanning. The greatest drawbacks with MRI are the long scan times and the claustrophobic environment that it demands. These imaging modalities should be complemented by the free use of fine-needle aspiration cytology. The latter is operator dependent but experienced cytologists can achieve accuracy rates of 87–96%.²⁷⁸ Best results are obtained when cytologists and radiologists work together which reduces the incidence of negative taps. The application of FNAC varies between clinicians. It has an obvious role in distinguishing benign from malignant disease but in many incidences a malignant disorder will be suspected on clinical grounds alone. In high-grade disease an open or Tru-cut biopsy is the investigation of choice. Paradoxically FNAC has a particular role when tumor is not anticipated. Thus in childhood, many lumps are inflammatory in origin and FNAC may avoid the need for parotid surgery. Similarly it will detect tuberculosis and if a benign tumor in an elderly or infirm individual can be confirmed then surgery can be avoided.⁴

It is important that all submandibular masses undergo FNAC. When compared to the parotid, the risk of encountering a malignant tumor is greater (34–50% vs 6–15%) but more importantly submandibular gland cancers carry 20% worse prognosis for no other reason than they are frequently misdiagnosed and inadequately excised.²⁷⁹

One other specific indication for FNAC lies in children with a suspected parotid tumor. Salivary tumors are uncommon in childhood but the risk of encountering a malignant tumor is greater than in the adult (34% vs 10%). It is imperative to try and avoid adjuvant radiotherapy in this group and if the surgeon is forewarned every attempt can be made to obtain adequate clearance to minimize the need for radiation therapy.

Intraoperative facial nerve monitoring

Superficial parotidectomy (SP) is little more than a dissection of the nerve. It is therefore not surprising that intraoperative neurophysiological monitoring

has been advocated in this type of surgery.²⁸⁰ It seems that for experienced surgeons, the incidence of facial nerve injury is not reduced,²⁸¹ but the technique may be an advantage for those in training. The medico-legal dimension of monitoring cannot be ignored, the equipment is relatively inexpensive, easy to use, minimally invasive, and may on occasion reduce the extent (rather than incidence) of nerve injury through constant feedback during surgery.

Benign parotid tumor

The majority of benign tumors are represented (93%) by two histological types – pleomorphic adenoma (71%) and Warthin's tumor (22%). In the last decade there has been a fundamental reappraisal of these two tumors. Pleomorphic adenomas had a fearful reputation for recurrence, which is not deserved, and the rationale for wide excision (SP) was based on this reputation. Similarly it is now appreciated that Warthin's tumor is a polyclonal lesion and not a neoplasm, which may manifest with synchronous or metachronous lesions. In both instances a more conservative approach to treatment is possible.

The traditional surgical approach to benign parotid tumors is a superficial parotidectomy (SP) and that for deep lobe tumors is a total parotidectomy (TP). Modern modifications include partial superficial parotidectomy and selective deep lobe parotidectomy.²⁸²

Traditional parotidectomy

An essential step in traditional superficial parotidectomy is the identification of the facial nerve and a prerequisite for safe surgery is wide exposure. This is achieved through a variety of preauricular incisions (lazy S: facelift). It is a useful exercise to release the parotid gland from the confines of the deep cervical fascia by freeing the fascia from the sternomastoid muscle, mastoid process, and tragus (the greater auricular nerve is ideally preserved). The increased mobility allows tumors wedged between the mandible and the mastoid to become more accessible. Using the avascular pretragal plane of dissection, the parotid is displaced anteriorly to identify the facial nerve. The main trunk is located halfway between the bony external auditory meatus and the tip of the mastoid at the medial aspect of the tympanomastoid fissure. The extent of the nerve dissection is governed by the location of the tumor. If the tumor is small only a quadrant of the parotid gland need be removed (partial superficial parotidectomy). Parotid surgeons should be equally adept at both retrograde and antegrade nerve dissection.

A total parotidectomy (TP) accompanies tumors deep to the facial nerve where the exposed branches of the nerve are lifted to access the tumor. With this additional stripping of the nerve comes an increased risk of permanent and temporary nerve injury (SP

1–2% permanent, 30% temporary vs TP 4–6% permanent, 60% temporary). Occasionally a parotid tumor extends into the parapharyngeal space and is usually removed following a total parotidectomy. This may necessitate a vertical submandibular osteotomy and division of the stylomandibular ligament or posterior belly of the digastric, either alone or in combination in order to improve access. Once these binding structures are released the tumor can usually be displaced inferiorly, where by necessity it is freed by a form of extracapsular dissection. In experienced hands this is a safe procedure and no adjuvant radiotherapy is warranted.

Extracapsular dissection

The practice of surgery in general is moving down a minimally invasive pathway and in the parotid this has found expression in extracapsular dissection (ECD) of benign parotid tumors. A minimally invasive approach challenges the concepts underpinning traditional parotidectomy and is still contested. The paradox is that as early as 1984, Donovan and Conley²⁸³ noted that 60% of benign salivary tumors came to rest on the facial nerve and when peeled from the tumor surface there was no increased risk of recurrence. The Christie series of 380 patients treated by ECD (median follow-up of 15 years) had a recurrence rate of 1.6% which matches SP but with significantly reduced morbidity.²⁸⁴

ECD should be reserved for discrete benign parotid lumps (>2 cm diameter) in the superficial portion of the parotid gland. The nature of the lump should be confirmed by FNAC for the main risk in ECD is not tumor recurrence but the inadvertent treatment of a low-grade malignant salivary gland tumor masquerading as a benign lump. This risk is greatest in small lesions as they have not had time to express their clinical nature and small lumps can be missed on FNAC.

The initial surgical approach and exposure of the parotid is similar to that for superficial parotidectomy (Fig. 36.23) with the preauricular skin flap raised to a point 1 cm peripheral to the tumor margin. A cruciate incision is made over the surface of the tumor and, by applying tension by way of artery clips attached to the parotid fascia, an areolar plane can be developed by careful blunt dissection at points around the tumor. A careful bloodless field accompanies this surgical plane at 1–2 mm peripheral to the tumor capsule. By moving it slowly from side to side, the tumor is gradually released but the procedure is not based on a nerve dissection so the nerve is not exposed unless it comes into the surgical field. Intraoperative facial nerve monitoring can be used for security. Once the tumor is removed the parotid fascia is reapproximated obliterating the defect, so minimizing the risk of Frey's syndrome, and leaving a normal parotid contour. In the majority of cases (60%) the greater auricular nerve can be preserved. It is advisable to

Fig. 36.23 ECD is a careful dissection, peripheral to the tumor capsule.

apply a pressure dressing for 48 hours post-surgery to reduce the risk of sialocele.

The data relating to ECD at four institutes (Guy's, Erlangen, Christie Hospital, Wythenshawe Hospital) were collated (Table 36.23). Outcome indices (permanent/temporary facial nerve injury, Frey's syndrome) are similar between groups suggesting that results achieved in more recent series are paralleling those with long follow-up. The accumulating data suggest that conservative procedures are safe when treating benign parotid tumors. ECD represents the limit of conservative surgery in the parotid gland.

Recurrences of pleomorphic adenoma

Recurrences of pleomorphic adenoma are nowadays uncommon following the abandonment of enucleation by the surgical community. Rupture of the tumor capsule may occur during surgery, especially if there is a significant myxoid component, or pseudopodia or satellite nodules in the "bare area". However macroscopic spillage carries only an 8% risk of recurrence, compared to 2.5% if no recognizable spillage was noted.^{285,286} Therefore the concept of spillage may not be as important as previously believed. Large tumors with a high S-phase fraction on flow cytometry are possibly more prone to recurrences.²⁸⁷

On average, recurrences occur 8 years after the initial treatment, presenting as either uninodular or multinodular lesions. MRI in combination with mandatory FNAC will confirm the recurrence of benign disease. Single nodules may be safely removed by nerve-preserving additional surgery, with a 15% risk of further recurrence at 10 years. Surgery alone is insufficient for the more common multinodular recurrences, which may be dispersed over the surgical field (Fig. 36.24). Forty-five percent of multinodular recurrences will recur within 10 years of surgical removal; adjuvant postoperative radiotherapy will

significantly reduce this to 4%.²⁸⁸ Malignant progression is very rare.

Revision surgery carries the risk of further trauma to the facial nerve which is proportionately dependent on the extent of the original surgical technique (ECD, SP, partial SP or TP). If this was either a SP or TP, the facial nerve will lie immediately inferior to the subcutaneous tissues within scar tissue. In these circumstances, the risk of permanent injury to the facial nerve is up to 60%. Even with nerve monitoring, facial nerve identification may be difficult. Skin replacement may be necessary for nodules adherent to skin. If on the other hand ECD or partial SP was performed for a tumor located in the parotid tail, the risk would be 15%.²⁸⁸

If the benign nature of the lump has been ascertained, and there is a significant risk of nerve damage, conservative management is acceptable in patients who are over 65 years old and in poor physical health.

Benign tumors of the submandibular and minor salivary glands

A submandibular gland adenoma should be removed in continuity with the gland. The situation to be avoided is an adenectomy for apparent sialoadenitis when the lesion is a malignant tumor.

The commonest intraoral site for benign salivary gland tumors is the junction of the hard and soft palate. Most present as rubbery lumps and the diagnosis can be established by FNAC or ideally a dermatological punch biopsy. The latter retrieves a small core (2–4 mm diameter) of tissue without violating the tumor margins. Those tumors situated on the junction of the soft and hard palate do not require a through-and-through dissection into the nasal cavity but can be safely dissected in a subperiosteal plane. It is advisable to cover the raw area with a dental healing plate.

Table 36.23 Outcome data for 966 tumors treated by ECD at four centers. Results of units commencing ECD parallel those with extended follow-up, suggesting similar outcome of low recurrence and reduced morbidity.

Malignant tumors

In the last two decades there has been a gradual change in philosophy in the management of malignant salivary gland disease based mainly on the pioneering work of Spiro.^{289–291} Management traditionally relied on histological diagnosis (as proxy for grade/prognosis: see box overleaf) when deciding on treat-

ment,²⁹² whereas Spiro focused on the relationship of size rather than grade to outcome. The results were clearly better in patients with low-grade lesions; the presence of a high-grade tumor had no significant impact on survival unless the tumor was large (>4 cm in diameter). This concept revolutionized the approach to malignant salivary gland surgery and outcome data confirm (Table 36.24) that treatment

Table 36.24 Clinical factors linked to outcome on multivariate analysis (P, parotid; SM, submandibular).

should be governed more by stage rather than histological type. The implication is that treatment has to be individualized for each patient.

Grading of tumor

The grade of a tumor is supposed to reflect its inherent biological nature (aggressive, intermediate or indolent). The term has been used loosely with more than one origin. Salivary carcinomas are classified into histological types or families (adenoid cystic carcinoma, mucoepidermoid carcinoma, etc.). The majority (but not all) of tumors in the family have a similar biological nature and certain families are known to be high-grade or biologically aggressive neoplasms (anaplastic carcinoma, carcinoma ex-pleomorphic adenoma, etc.). Others are recognized as low-grade tumors (acinic cell, low-grade adenoid carcinoma, etc.).

In addition it is possible to use histological features to identify a subgroup of tumors that signify a more aggressive behavior. This is the case for mucoepidermoid carcinoma which can be divided by histological features into high, middle, and low grade.

The last method of determining the biological nature of the tumor and the most reliable is assessment of the clinical features of aggression, such as rapid change in size, infiltration, metastasis. These are currently incorporated into the present staging system of salivary cancer. The latter has taken over from histological type and histological grading as the most important prognostic factor determining treatment.

Malignant parotid tumors

The object of treatment is to excise the tumor with an adequate rim of normal tissue but this may not be possible because of the complex anatomy of the parotid area and emphasizes the practical nature of the 4 cm rule, as adequate surgical clearance of tumor is not possible with large masses.³⁰⁴ It is for this reason that adjuvant radiotherapy plays an important part in the management of salivary gland cancer.³⁰⁵ Wherever possible a functioning facial nerve should be retained except if completely immersed in tumor. The traditional approach to a malignant parotid tumor is a total parotidectomy. With experience this dogma can be softened and small (stage I) well defined tumors, particularly in the tail of the parotid, can be excised with an adequate normal parotid tissue to make a total or even a superficial parotidectomy unnecessary.^{306–308} In contrast if a facial nerve palsy is already present then a radical parotidectomy is a logical option. If the facial nerve has to be resected, ideally it should be reconstructed at the same operation.

Submandibular gland

The literature demonstrates that submandibular gland cancers carry a 20% worse prognosis than malignant tumors in the parotid or mouth.²⁷⁹ Initially this was attributed to a higher incidence of adenoid cystic carcinomas in the submandibular gland. However Spiro showed this not to be the case. An appropriate oncological procedure as the primary

procedure restores the survival rate to that achieved in both the mouth and the parotid.

Minor salivary gland tumors

Minor salivary gland cancers within the oral cavity are managed in the same way as squamous cell carcinomas in the mouth.

Radiotherapy

A single center retrospective series³⁰⁹ and a matched-pair analysis³¹⁰ demonstrated improvement in local control when a combined approach was compared with surgery alone. Analysis of results of the Christie Hospital^{311–313} also showed significant reduced local regional recurrence (16% vs 62%) and significantly improved 5-year survival (63% vs 73%) in tumors >4 cm with adjuvant radiotherapy. It is generally acknowledged that adjuvant radiotherapy reduces local recurrence but does not have a significant impact on overall survival due to distant metastasis. There is emerging evidence, however, that in biologically aggressive tumors survival may be improved by adjuvant radiotherapy.

Neutron beam therapy was used in the 1980s and 1990s in the treatment of head and neck cancer but was subsequently abandoned because of severe tissue reaction and complications following treatment. Radiobiological effectiveness of neutron beam therapy is superior to that of traditional photon therapy for salivary gland tumors.^{314,315} In view of the history of unacceptable normal tissue morbidity following neutron beam therapy the number of operational neutron facilities is limited. Consequently photon therapy is likely to remain the principal form of adjuvant therapy to support surgery.

Chapter 37

Outcomes of Management of Oral Pathologic Lesions

Simon N. Rogers and Kalyan Voruganti

This chapter will aim to cover the general outcomes of oral pathologic lesions with particular emphasis placed on oncology. The main outcomes are survival, complications, quality of life, and function. These will be explored in detail to give the reader an understanding of how these impact on the maxillofacial patient.

Introduction, 775

Survival, 776

Tumor recurrence rates, 777

Complications, 777

Adult respiratory distress syndrome (ARDS), 777

Deep vein thrombosis (DVT), 777

Donor site morbidity, 777

Free flap loss and flap salvage, 778

Length of stay (LOS), 778

Plate infection and removal, 778

Readmission, 778

Postoperative radiotherapy, 781

Soft palate resection, 781

Tumor resection, 781

Conclusion, 781

the disease, the consequence of surgical intervention, and the patient's perception of this.

Outcomes are fundamental to all aspects of oral and maxillofacial surgery ranging from dentoalveolar, orthognathic, trauma, and oncology. This chapter will focus on outcomes following complex benign and malignant lesions. Although there is a vast range of pathologic conditions, they share a common outcome. The main outcomes discussed are survival, complications, patient-derived (health-related quality of life), and function (Table 37.1). However, there is a notable difference between complex benign and malignant lesions, that of survival. Although unexpected tragic death can occur following surgery for benign disease, in the cancer situation the poignancy of recurrence and death from disease is reality. In oncology survival is of paramount consideration for patients.^{1,2} There is a better outcome with early-stage disease (stage 1 and 2) but this chapter does not intend to address issues related to earlier detection and referral of pathologic lesions.

There are various ways of measuring outcome, both objective (clinician rated) and subjective (patient derived) (Table 37.1). The objectively scored evaluations include measurements from radiographs or study models, or the presence or absence of a specific outcome such as a gastrostomy tube. Specific complication rates for certain operations might also be pertinent and vary depending on the surgery, for example facial nerve weakness following superficial parotidectomy. Indirect indicators may be related to outcome such as length of hospital stay (LOS). The problem with LOS is that, although it might reflect surgical complications, it is influenced by many other factors such as age, comorbidity, family support, and social deprivation. Thus it is essential to incorporate case-mix factors for certain outcomes such as perioperative mortality. The patient-derived assessments (subjective) are usually measured by questionnaires. These can provide quantitative (numbered) data that are easier to handle than qualitative (open interview) approaches. Although difficult to measure, the patient's perspective must be borne in mind, as this

Introduction

The aim of this chapter is to discuss outcomes of both complex benign and malignant lesions of the oral cavity. Pathologic lesions within the oral cavity and adjacent structures can arise from a variety of tissues such as mucosa, salivary glands, bone, and tooth tissue. The outcome relates to the natural history of

Table 37.1 Main outcomes.

Outcome	Examples
Survival	Overall, disease specific, recurrence, locoregional (i.e. around a local region) control rates
Complications	Relapse, deep vein thrombosis (DVT), wound infection, plate removal, free flap success, fistula, etc.
Patient derived	Health-related quality of life, function specific, satisfaction
Function	Paresthesia, movement of tongue, mouth-opening limitation, pain, speech difficulty, swallowing difficulty
Indirect	Length of hospital stay, readmission rates

Table 37.2 Value of patient-derived outcome data.

Person who might find patient-derived outcome of value	Reason for the patient-derived data
Clinician	To demonstrate that the treatment has been effective
Hospital	Successful treatment for groups of patients
Financers for treatment/insurance companies	To include the patient's perspective in the evaluation of the most cost-effective treatment
Government bodies/health improvement agencies	Compare outcomes between different surgeons, departments, and hospitals
Employer	Successful treatment reduces the time taken to recover and be absent from work
Researcher	Statistical comparison of different treatments
Statistician	95% confidence limits, i.e. to show treatment works intentionally and not by chance
Patient/carer	Informed decision making, improvement of symptoms

can be crucial to “success” or “failure” from the patient’s viewpoint. It is recognized that there are patients who have an excellent outcome following surgery yet have a lot of concerns and are far less happy with the result than other patients with a similar objective outcome. Conversely, some patients who have a poor surgical outcome report relatively little dysfunction and high degree of satisfaction. In part this reflects different personalities and expectations.

To fully address the issue of outcome it is worthwhile combining both elements of objective and subjective measures. This is well demonstrated in an early paper by Brown *et al.*³ where the benefit of using a pharyngeal flap in combination with a radial forearm free flap to reconstruct the soft palate after tumor ablation was evaluated. The outcomes include a validated head and neck specific questionnaire (University of Washington Quality of Life Scale), intelligibility

(clarity of speech scoring by both speech therapists and lay listeners), and videofluoroscopy. These multiple modalities combined give a clear indication of the potential benefit of using a pharyngeal flap when the resection involves more than half of the soft palate. As shown later in this chapter a similar detailed approach was used by Devine *et al.*⁴ to compare outcomes following two different surgical oral access procedures: lip split mandibulotomy or visor/dropdown.

Outcome data are useful to many different people (Table 37.2). They help to underpin clinical audits, local protocols, national guidelines, and clinical research. A challenge is that outcome parameters can vary markedly between units and countries, and this makes comparison problematic. It is important for groups and “associations” to agree a workable dataset with common outcome parameters that are reproducible. Ideally the measures should be simple and the process not arduous. There are several examples of nationally agreed datasets such as DAHNO (data for head and neck oncologists) in the UK.

Survival

Relatively few institutions have reported survival data for their patients with oral cancer (squamous cell carcinoma) and this probably reflects the diligence required in collecting accurate data. Survival can be considered as crude (overall) or disease specific (i.e. related specifically to squamous cell carcinoma for example). Some older papers predate the widespread introduction of microvascular reconstructive techniques.^{5,6} Reports exist from various other countries such as Australia, Denmark, Taiwan, USA, Norway, Japan, South Korea, Germany, and the UK.⁷

Survival can be related to prognostic factors such as age, stage, and histopathological criteria.^{8–12} Other factors may also play a role, for example blood transfusion and free tissue transfer¹³ for patients with mandibular invasion¹⁴ and adjuvant radiotherapy for patients at an intermediate risk of recurrence.¹⁵

Accurate survival data are critical for many reasons. These data aid treatment protocols, tumor board discussions, and individual patient and carer decision-making. Data from the authors’ unit (University Hospital Aintree, Liverpool) show that of 541 consecutive patients with oral squamous cell carcinoma seen between 1992 and 2002 only 10% received primary radiotherapy.⁷ In the unit the favored curative treatment is radical primary surgery. Those patients who had primary radiotherapy tended to be older, with additional comorbidity and with more advanced disease. This was reflected in an overall poorer survival at 5 years, 23% (SE 7%). In the 489 patients who had primary curative surgery, 40% received adjuvant radiotherapy. The overall survival (OS) was 56% (SE 2%) and the disease-specific survival (DSS) was 74% (SE 2%). Five year DSS for pT1 tumors was 96%, pT2

was 82%, pT3 was 78%, and pT4 was 57%. There was a local recurrence rate of 10% and the locoregional recurrence rate was 21%. The second primary rate was 7%. Survival figures had improved over the 10-year period from 63% DSS for the first 4 years of the study (1992–1995) to 81% for the last 3 years (2000–2002). In stepwise Cox regression the two predictors selected for DSS were pN status and margins (both $p < 0.001$). Age–sex mortality rates for the north-west of England indicate that 15.0% of the 489 primary surgery patients might have been expected to die within 5 years if they were typical of the general population and the observed difference between all causes and oral cancer specific survival was 18.3%. These data emphasize the value of DSS as an indicator of successful treatment in a cohort that tends to be elderly, from social deprived backgrounds, with life styles and comorbidity that influence overall survival.

Tumor recurrence rates

Both benign and malignant pathologic conditions have the potential to recur. Although uncommon and arising over a long time period, it is important that recurrence rates following surgery for benign disease are recorded as accurately as possible. For example, recurrence is seen with parotid gland neoplasia (pleomorphic adenomas), odontogenic cysts (keratocystic tumors), and odontogenic tumors (ameloblastomas). Likewise local recurrence rates following locally aggressive lesions such as odontogenic tumors (ameloblastoma) are a significant outcome.

With malignant disease recurrence rate usually reflects ongoing disease in terms of local, regional, and metastatic spread.⁷ Regional (neck) recurrence is one of the commonest sites and this is linked with the rate of clinically and radiologically undetected nodes at presentation tends to support the use of selective neck dissection even in relatively early oral cancer. There is some uncertainty, about which patients benefit from adjuvant radiotherapy following primary surgery.¹⁵ As discussed later in the chapter, there are probably more opportunities for salvage in patients treated by surgery alone. Second primary tumors may also arise from an area of field change (adjacent dysplastic tissue). The issue of second primary tumors rates has become of concern as a consequence of the success of primary treatment and increase in longevity in this patient group.

Complications

Complication rates are another key outcome parameter following surgery. These can be considered as immediate, early or late, and are also general or site specific. There are many different complications following surgery to the orofacial region. This is illustrated following parotidectomy where facial nerve

impairment, greater auricular sensory deficit, gustatory sweating (i.e. sweating on salivation), and pain are all pertinent outcome parameters. These can therefore impact on the patients' perception of success.¹⁶ It is usually easier to record complications immediately postoperatively, such as facial nerve weakness in the case of a parotidectomy, when patients are on the ward or at their first outpatient review. With longer-term outcomes patients tend to get lost to follow-up or are missed. It is difficult to get long-term data as assessment at a specific time point is often forgotten. However facial nerve weakness can take many months to improve so long-term outcome data are essential. This chapter will not attempt to list all the possible complications that might make a suitable indicator of outcome for the various different pathologies and interventions; a relatively few general examples (in alphabetical order) are considered for illustrative purposes.

Adult respiratory distress syndrome (ARDS)

This is defined as *"the pulmonary manifestation of a widespread abnormality of cellular metabolic function"* and was first described by Ashbaugh *et al.* in 1967.¹⁷ ARDS is associated with mortality following major surgical procedures. It has been linked with large-volume blood transfused in 48 hours and a return to the operating theater for early complications. Change in perioperative practice in relation to fluid management and mechanical ventilation seems to have all but eliminated this event.^{18,19}

Deep vein thrombosis (DVT)

This is a complication usually related to prolonged operations such as orthognathic and oncology surgery. Blackburn *et al.* carried out an audit of DVTs following osteotomies in 129 patients over 4 years.²⁰ Two cases had DVT confirmed by venography with neither having a pulmonary embolus. Clagett *et al.* showed a 25% incidence of DVT in postoperative patients who had no prophylactic measures.²¹ This highlights the value of prevention by using local measures such as antithrombotic stockings and low molecular weight heparin.

Donor site morbidity

The radial forearm free flap is the commonest source of free tissue transfer for reconstruction of the maxillofacial region. This reflects its relatively easy harvesting and its versatility. It also has a long vascular pedicle with large-caliber vessels if raised with the cephalic vein, and minimal donor site morbidity. It is particularly useful in the oral cavity. There are various complications that have been reported, such as partial loss of the donor-site skin graft, exposure of tendons, fracture of the radius with composite flaps,

and reduction in superficial radial nerve sensation.²² Fracture of the radius is associated with a poor functional outcome. Care is required during the harvesting of bone, and plating and immobilization have been advocated to help prevent this complication.

Free flap loss and flap salvage

Free tissue transfer has an established role in the reconstruction of patients following tumor ablation and tissue loss. The success of the free flap is critical from a functional perspective and for health-related quality of life. A non-viable flap has to be removed and the defect reconstructed by another free flap or alternative method. This leads to additional morbidity and prolonged hospital stay, and tends to delay the timing of adjuvant radiotherapy. This in turn can impact on cure rates. Flap success rates are decreased in patients who have had previous neck surgery or radiotherapy, those with comorbidity, and patients who have composite reconstruction. Site is also a factor, with the maxillary defect being one of the most difficult given its composite nature, the length of pedicle required, and the quality of the feeding artery and draining vein. Early identification of a compromised flap increases the likelihood of successful salvage.²³ Grant *et al.*²⁴ have reported that the acute physiology and chronic health evaluation (APACHE II) score is a good predictor of early postoperative surgical complications but how useful this is in clinical practice is unclear.

Length of stay (LOS)

This can be used as a surrogate indicator of complications. It is, however, influenced by several other factors such as age, comorbidity, and social circumstances. Although LOS is a relatively non-specific outcome it is often used because there are cost implications to hospitals with regards to time spent in a hospital bed and it is an easy outcome to measure. Rogers *et al.* examined the relationship between LOS and health-related quality of life and found increased LOS to be associated with worse health-related quality of life.²⁵ This was confounded by age, which influences the LOS more than health-related quality of life.

Plate infection and removal

For mandibular defects, reconstruction usually involves titanium miniplates or reconstruction plates. If infection occurs the offending plate(s) must be removed. Shaw *et al.* compared complication rates of miniplates versus the larger reconstruction plates in the fixation of vascularized bone grafts into segmental mandibular defects involving 143 vascularized composite free flaps placed over an 8-year period.²⁶ Forty-nine percent had miniplate placement and 51% had reconstruction plates; 27% of miniplates and 30% of reconstruction plates required removal for infec-

tion. There was no statistically significant difference between the plate types.

Readmission

Readmission rates are sometimes used as an outcome parameter. Like LOS they are non-specific as readmission might not necessarily reflect a complication or indicate the need for further surgery or recurrence. Readmission could be for pain control, nutritional support or for other non-surgical reasons.

Wound infection rates

Wound infections, although not often of major significance in terms of mortality, cause delayed and less satisfactory healing. There are many pathogens which can be involved, such as hemolytic streptococci, but it is methicillin-resistant *Staphylococcus aureus* (MRSA) that is currently under the most intense scrutiny. Rogers *et al.* reported an MRSA rate of 1% on a maxillofacial ward.²⁷ The vast majority occurred in oncology patients where the rate was 14% and the significant risk factors were found to be the stage of cancer and whether free flap surgery was involved. Another notable pathogen is *Clostridium difficile* – a toxin-producing, Gram-positive anaerobe that has been implicated as the causative agent of pseudomembranous colitis. This is an acute inflammatory bowel disease that generally occurs in association with antimicrobial therapy.²⁸ This pathogen can have grave implications for patients. Further issues arise regarding cross-infection control, such as hand washing, screening and segregation of patients, inappropriate use of antibiotics, and wound dressings. These all need further evaluation specifically related to a maxillofacial setting and how they affect wound infection rates.

Patient-reported outcomes

It is important to use patient-reported outcomes (PRO) as there can be marked differences in perspectives between doctors and patients. Doctors tend to overestimate the objective symptoms and underestimate more subjective problems.²⁹ Concerns of patients can easily be missed.³⁰ The various ways of measuring patient-derived outcomes are given in Table 37.3. The main difficulties in asking patients to fill in questionnaires are logistical such as lack of resources, time, and manpower as well as inexperience with questionnaire use.³¹ Computers offer a practical solution, using touch screen technology³² to help collect PRO in terms of health-related quality of life outcomes.

Table 37.4 gives examples of the different groups and types of questionnaires available. There is no gold standard questionnaire and each has unique features, strengths, and limitations.^{33,34} Questionnaires

Table 37.3 Methods of measuring patient-derived outcomes.

Approach	Indication
Simple questionnaire	Takes less than 10 minutes for patient self-completion Useful for postal survey with good response rates Ideal for telephone survey
Semi-structured interview	Patients are assisted to complete a battery of questionnaires The questionnaires can be more complicated in structure and thus provide more information Discussion of issues adding weight or importance to the items to develop a patient-generated index (PGI) or trade-off to build a utility value
Open interview	Loose structure to the interview allowing the patient to report many different issues and the opportunity to explore these in more depth Useful for item generation as a first step in questionnaire development Used in conditions where the scope of the issues is very wide, such as palliative care

Table 37.4 Different groups of questionnaires and examples of each. Each abbreviation mentioned is the name of a questionnaire tailored to measure a specific aspect, e.g. cancer or function, etc. There is a plethora of these tools available and those shown here are merely a small sample. For further information please see references 33, 34, 67, 68.

Group	Questionnaire name
Performance	Karnofsky, ECOG
Global/generic	SF-36, HAD, CESD, EQ-5D
General cancer	EORTC-C30, FACT-G
Head and neck cancer specific	EORTC H&N, FACT HN, UW-QOL
Function specific	Appearance (Derriford) Oral rehabilitation (LORQ) Saliva (XEQoLS) Shoulder (NDI, SDI) Speech (VHI, V-RQOL) Swallowing (SWAL-QOL, MDADI)
Others	Body image, coping, distress, emotion, family, fatigue, information, pain, personality, satisfaction, self-esteem, social support, spirituality

must be validated. A commonly used broad head and neck cancer questionnaire is the University of Washington quality of life tool (UW-QOL). The UW-QOL was first published in 1993³⁵ and is currently in its fourth version.³⁶ There have been recent additional questionnaires that have focused on specific issues in more depth, such as swallowing, speech, and dry mouth. There is now a substantial body of published material on the subjective outcomes following oral and oropharyngeal cancer.³⁷ Table 37.5 shows the key issues. Outcomes are associated with patient characteristics such as age, the tumor itself, the patient's

lifestyle, and factors relating to the surgery and/or radiotherapy.³⁸

It is better to choose a validated questionnaire for audit or a research proposal where possible, as study-specific questions lack validity and comparison with other studies. Questionnaires exist to test nearly every aspect of oral and maxillofacial surgery, including esthetic surgery, cleft lip and palate, craniofacial surgery, dentoalveolar surgery/third molars, distraction osteogenesis, facial pain, oncology, oral medicine and oral mucosal disorders, orthognathic surgery, pre-prosthetic surgery and dental implants, reconstructive surgery, salivary gland disease, skull base surgery, temporomandibular joint, and trauma.

Function

The functional outcome of disease is a key factor as a consequence of the treatment. This affects patients' acceptance and quality of life.³⁹ The relationship between function and health-related quality of life was explored by Rogers *et al.* by using an 11 point examination.⁴⁰ Factors assessed included lip competence, speech, drooling, lip and tongue sensation, and shoulder movement. Patients who had large tumors, free tissue transfer or adjuvant radiotherapy (i.e. radiotherapy post surgery) were found to have a worse level of function. This was associated with a lower health-related quality of life. Clinical examination combined with validated questionnaires provides a useful predictor of outcome. Detailed information such as this can help patients to reach a decision in treatment choice and is a useful adjunct to informed consent.⁴¹

Information and clinical outcomes research has given valuable insight into various aspects of oncology and has helped to shape clinical practice. Both objective and patient-derived data can be used. The following are examples to illustrate the issue.

Access

Good access to facilitate tumor ablation is an essential prerequisite for a safe resection. There can be a choice between lip-split with a mandibulotomy versus a mandibular lingual releasing technique (Fig. 37.1). In a detailed study combining objective and subjective measures of outcome between these two methods, Devine *et al.*⁴ showed that there was no obvious difference in objective function or in appearance. However on subjective data the lip split mandibulotomy group reported significantly better speech, swallowing, and chewing.

Bone flaps

The choice of the most suitable reconstruction following extensive jaw resection is often between a deep circumflex iliac artery (DCIA) flap or a fibula flap. Both objective and subjective evaluation of outcome would suggest that both flaps are well tolerated with generally acceptable morbidity.⁴² However when a significant complication occurs it tends to have a very detrimental effect on health-related quality of life in both groups. The choice of either flap is based on the one that offers the most optimal reconstruction.

Mandibular resection

The issue of segmental resection or rim resection of a mandible in tumor removal has been informed by subjective outcome data.⁴³ Preoperatively patients undergoing segmental resection reported significantly more pain, chewing problems, and a lower composite UW-QOL score. Postoperatively the segment group tended to score worse at all time points, particularly in appearance, swallowing, recreation, and chewing. However, the difference between rim and segment was only seen in smaller resections without adjuvant radiotherapy. Little difference was seen between rim or segment for tumors <4 cm with radiotherapy and also between rim and segments for tumors >4 cm. Young *et al.* examined the health-related quality of life for patients undergoing

Fig. 37.1 Lip split mandibulotomy: free flap being inset following tumor ablation.

mandibular resection with immediate insertion of a reconstruction plate and subsequent staged reconstruction.⁴⁴ The staged reconstruction involved bone grafting, removal of the reconstruction plate, vestibuloplasty, implant insertion, and construction of an implant-supported prosthesis. Appearance was a key concern with segmental resections and might affect females more than males and could explain their decreased health-related quality of life.

Maxillectomy

The maxillectomy defect can be obturated using a prosthesis or reconstructed with free tissue transfer. Over time, following patient adaptation and careful clinical support, there might not be that much difference between the two approaches from the patient's perspective.⁴⁵ It is probable that primary free tissue reconstruction is associated with better health-related quality of life outcomes.⁴⁶

Neck dissection

In the management of oral and oropharyngeal cancer the selective neck dissection has an established role. This is based on the possibility of occult (i.e. hidden) lymph node metastasis not evident clinically or obvious on pretreatment imaging.⁹ From the patient's perspective a selective neck dissection causes relatively little morbidity compared to other health-related quality of life aspects⁴⁷ and is not as important as other issues such as speech, chewing or swallowing.⁴⁸ A functional neck dissection can be associated with more clinician-rated deficits than with problems reported by the patient.^{49,50} Further outcome studies are required on the role of a "wait and watch" or sentinel node biopsy policy. Sentinel node biopsy involves a dye and radioactive tracer being injected into the tumor field and traced. The first group of lymph nodes reached (sentinel nodes) are then removed, minimizing the need for a selective neck dissection.

Oral rehabilitation

Oral rehabilitation has an important role in promoting quality of life following reconstructive surgery.^{51,52} A relatively small proportion of patients require implant-retained prosthesis.⁵³ The Liverpool Oral Rehabilitation Questionnaire (LORQ) helps give more precision to the subjective evaluation of outcome.^{54,55} The factors associated with the success of implants have been assessed and the necessity of hyperbaric oxygen in an irradiated field has been brought into question.⁵²

Percutaneous endoscopic gastroscopy (PEG)

Nutritional support is an important consideration for patients undergoing surgery who already have pre-

existing weight loss and might have problems with swallowing. The benefit of percutaneous endoscopic gastroscopy (PEG) has to be weighed up against the potential morbidity and mortality. Insertion can cause peritonitis and there is the potential risk of PEG site seeding (i.e. seeding tumor cells from the primary site into the gastrostomy site during placement). Patients with long-term PEGs have been found to have a significantly worse health-related quality of life.⁵⁶ This is because those patients who require a PEG usually have advanced disease requiring radical treatment (combined surgery and adjuvant radiotherapy or chemoradiotherapy). The main problems encountered by patients, however, are not related to tube blockage, leakage or discomfort, but are due to broader aspects such as interference with family life, intimacy, and hobbies.

Postoperative radiotherapy

Choosing which patients need postoperative radiotherapy is a topic of much debate. Brown *et al.* examined 462 patients treated by primary surgery, with or without radiotherapy;¹⁵ 29% were at low risk of disease recurrence, 29% were at high risk, and 42% were at intermediate risk. For those at intermediate risk the 5-year survival was 54% for those receiving radiotherapy vs 71% for those treated with primary surgery alone. There was found to be a higher rate of locoregional recurrence in the radiotherapy group and a lower salvage rate compared to the surgery alone group. There are therefore potential disadvantages associated with the use of postoperative radiotherapy in the intermediate risk group. A randomized control trial is required to adequately evaluate the benefit of radiotherapy in the intermediate risk group. Patients needing combined treatment have a significantly poorer health-related quality of life outcome⁵⁷ and the main issues relate to the problems associated with xerostomia, swallowing, and trismus. Trismus can be commonly overlooked but can have a profound affect on a patient's chewing, diet, and overall quality of life.⁵⁸ It is more effectively evaluated as an outcome by combining measurement (35 mm cut off) and a single item question, e.g. "How much has your mouth opening decreased since treatment". Intensity modulated radiotherapy (IMRT) reduces the degree of salivary dysfunction and it is hoped it will give a better outcome from the patient's perspective in the future.

Soft palate resection

In some centers radiotherapy is the first choice of treatment for tumors at this site. Brown *et al.* showed that regardless of the size of tumor, primary surgery has a favourable outcome.⁵⁹ Speech, chewing, and swallowing were similar regardless of resection size. Speech and swallowing outcomes have been further reported by Zuydam *et al.*^{60,61} As described earlier in

the chapter if over half the soft palate has been resected, a superiorly based pharyngeal flap is recommended.³ Both objective and subjective outcome data would concur. It is believed there may be shrinkage of a free flap, especially postradiotherapy, leading to velopharyngeal incompetence, which a superiorly based pharyngeal flap helps to prevent.

Tumor resection

The surgeon performing tumor ablation aims to get an adequate margin of clearance to prevent recurrence. Where possible laser excision or primary closure (i.e. closure at the time of surgery) gives superior functional and health-related quality of life outcomes than free tissue reconstruction.⁶² This is particularly notable for the speech and swallowing outcomes for oropharyngeal and posterior one third of tongue tumors.^{60,61} In recognition of this the proportion of patients having free flaps has reduced⁶³ without any notable increase in local recurrence rates or poorer survival.

Conclusion

The evaluation of outcomes following treatment for complex benign and malignant lesions has a crucial role in clinical practice. The main outcomes are survival, complications, patient-derived quality of life, and function. Patient-derived outcomes give the patients and clinical team much better information on expected outcomes.^{64,65} The assessment is made much stronger when objective (clinician-rated) and subjective (patient-derived) data are used in combination. These data can help to shape clinical practice in each unit, aid national protocols, and inform the clinical research agenda.

Chapter 38

Assessment of the Injured Patient

Brian Bast

This chapter gives an overview based upon on the guidelines for the initial evaluation of the trauma patient by the American College of Surgeons and detailed in the Advanced Trauma Life Support courses which in recent decades have been given worldwide and attended by many oral and maxillofacial surgeons.

Secondary survey, 795
Conclusion, 796

Trauma is a global problem and continues to be a leading cause of death and disability in both developed and developing countries. It is the leading cause of death in persons aged 1 through 44 years in most developed countries. Trauma caused more than 300 million patients to seek hospital care worldwide in 1990. It is projected to advance to the second leading cause of death in all age groups worldwide by 2030. Motor vehicle accidents are projected to rise to the fifth leading cause of death worldwide by 2030. Violence is also projected to increase in prevalence and by 2030 will be the sixteenth leading cause of death worldwide.¹ Many trauma patients brought to the hospital will have facial injuries requiring the care of an oral and maxillofacial surgeon.²

Oral and maxillofacial surgeons will always be involved in the evaluation and management of patients who have suffered facial trauma. Facial trauma encompasses a broad spectrum of disease. We may be called to treat the minor lip laceration sustained during a sports injury and in contrast we may be called to the trauma center to evaluate a patient with multiple facial fractures sustained during a roll-over motor vehicle accident. In both of these cases the patient may have other injuries that require diagnosis

and treatment. It is critical that the oral and maxillofacial surgeon has an understanding of the initial evaluation of the trauma patient and can ensure that the appropriate work-up was completed and more serious injuries were either diagnosed or ruled out.

This chapter will review the guidelines for the initial evaluation of the trauma patient established by the American College of Surgeons and detailed in the Advanced Trauma Life Support (ATLS) courses.

Development of the ATLS concept of trauma care

An orthopedic surgeon involved in a plane crash in the 1970s recognized the inadequate trauma care provided by a rural hospital in the USA. A group of local surgeons, emergency room doctors, and nurses, working with the Lincoln Medical Foundation and the University of Nebraska, took on the task of developing a course to ensure optimal care of the injured patient. The courses were initially designed for the physician who did not routinely evaluate and treat trauma patients. The idea was to provide clinicians with a skill set that could be used in more effective trauma evaluation and resuscitation. The first ATLS course was given in 1978 and 1 year later was adopted by the American College of Surgeons as an educational program. The ATLS courses are now in their third decade and are taught in over 50 countries worldwide. The principles have been taught to over 1 million physicians since 1990.³

The concepts adopted by the ATLS course were simple and represented a significant change from the traditional medical work-up of a patient. There was less emphasis placed upon an exhaustive history and detailed physical exam. The ATLS programs were built around three core concepts which represented a dramatic change in traditional “medical” thinking. The first concept defines the ATLS approach. Treat the greatest threat to life first. The loss of an airway kills faster than the loss of intravascular volume which kills faster than an acute intracranial bleed. This prin-

ciple is simplified as the “ABCDE” approach to the trauma evaluation. The second principle is that an indicated treatment should not wait for a definitive diagnosis. And third, an extensive history is not a critical component of the initial evaluation of the injured patient.⁴

Trauma centers and trauma systems

In the USA, and in many regions around the world, trauma care is provided by trauma systems with the goal of transporting injured patients rapidly to local trauma centers for care. Care systems ensure a coordinated effort from hospital emergency medical services and trauma hospitals. They ensure an efficient triage and transport to the trauma center for acute care and rehabilitation. Many studies have reported dramatically improved outcomes when injured patients are treated at trauma centers. Multiple studies suggest that when the most severely injured patients are treated at trauma centers there is up to a 50% decrease in preventable deaths.⁵

In 1976 the American College of Surgeons Committee on Trauma developed criteria for categorizing hospitals according to the level of trauma care available. Level one trauma centers provide comprehensive trauma care, serve as a regional resource, and provide leadership in education, research, and system planning. A level one center is required to have immediate availability of trauma surgeons, anesthesiologists, physician specialists, nurses, and resuscitation equipment. Level one classification requires that a center treats at least 240 major traumas per year. Level two centers also provide comprehensive trauma care either as a supplement to a level one center in a large urban area or as a lead hospital in a less populated region. Level two centers must meet essentially the same criteria as a level one center but volume standards are not required and centers are not expected to provide leadership in teaching and research. Level three trauma centers provide prompt assessment, resuscitation, emergency surgery, and stabilization with transfer to a level one or two center as indicated. Level three centers typically serve communities that do not have immediate access to a level one or two facility. Level four centers provide advanced trauma life support prior to transfer; they are in remote areas in which no higher level of care is available.

Level one and two trauma centers carry the highest clinical demands. The required clinical capabilities include general surgery, anesthesiology, emergency medicine, neurosurgery, orthopedic surgery, oral and maxillofacial surgery, plastic surgery, hand surgery, ophthalmology, obstetrics and gynecology, thoracic surgery, critical care medicine, cardiac surgery, and microvascular surgery.⁶

Initial treatment of the trauma patient

Triage

Deaths from injury are classically described as occurring in a trimodal distribution. The first peak is within seconds to minutes of the injury and is due to severe brain or spinal cord trauma, heart or major vessel rupture. These types of injuries are not survivable. The second peak occurs from minutes to hours after injury. Deaths during this period are due to progressive intracranial bleeding (subdural/epidural hematoma), organ system damage (pneumothorax, spleen or liver laceration), pelvic fractures, or other injuries associated with significant blood loss. The third peak occurs days to weeks after the injury and is due to sepsis or multiple organ system failure. There is some debate about whether deaths from injury continue to follow the classic trimodal distribution.⁷ What remains clear is that the vast majority of preventable deaths require rapid assessment and intervention. Multiple events need to occur efficiently in the “golden hour” to enable assessment and resuscitation.

Trauma care begins outside of the hospital. Emergency medical teams are often the first to evaluate injured patients. They are trained to rapidly triage (from French *trier* = sort) the patients, so priority is given to those patients and injuries which are most serious or require urgent treatment, and to determine if the patient’s injuries warrant transport to a trauma center. Triage criteria include vital signs and level of consciousness, types of injury, and mechanism of injury. During the initial evaluation if the injured patient shows a decreased level of consciousness, high or low respiratory rate, or low systolic blood pressure they are transported to a trauma center. If the patient has obvious severe injuries (flail chest, long bone fractures, penetrating injuries, skull fractures, paralysis, pelvic fractures, or burns) they are transported to the trauma center. If the mechanism of injury would suggest severe patient injury (ejection from auto, death of co-passenger, high speed crash, prolonged extrication time, falls greater than 6m, auto pedestrian injury, or motorcycle crash) the patient is taken to the trauma center. If the injured patient has underlying factors that could complicate the management of even minor injuries (age less than 5 or greater than 55, pregnancy, immunosuppression, cardiac disease, pulmonary disease, diabetes, cirrhosis, morbid obesity, or coagulopathy) the patient is taken to a trauma center. The overriding rule is “when in doubt take the patient to the trauma center”.⁸

A number of triage tools have been developed to aid in the rapid evaluation and determination if an injured patient should be brought to a trauma center. Although sensitive, specific, and predictive of out-

come in practice, these tools may be cumbersome and are rarely used. Two of these tools have become a standard component of many triage algorithms and have been validated in the literature. The Revised Trauma Score is a physiologic scoring system which uses the first set of data obtained from a trauma patient. It consists of Glasgow Coma Scale, systolic blood pressure, and respiratory rate.⁹ The Pediatric Trauma Score is a six-component scale that includes weight, airway, systolic blood pressure, central nervous system, open wound, and skeletal trauma.¹⁰ Both of these tools provide an absolute number that can aid in the triage process.

Emergency department preparation for the arrival of a trauma patient is a vital part of the triage process. A large resuscitation area should be designated for the patient's arrival. Airway equipment, warmed intravenous crystalloid solutions, monitors, and medical personnel should be immediately available. Radiology and laboratory evaluations should also be rapidly available.

Primary survey and resuscitation

Once the trauma patient is transported to the hospital they are taken to a trauma resuscitation room for rapid assessment. A team of doctors and nurses will work together to evaluate the patient's vital functions (Fig. 38.1). The patient is undressed, monitors are placed, intravenous access is established, and supplemental oxygen delivered. The overall management consists of a rapid primary survey, resuscitation of vital functions, a detailed secondary survey, and lastly the initiation of definitive care. The primary survey identifies injuries in a systematic fashion. The idea is to identify the greatest threat to life first and resuscitate accordingly. The treating physician is constantly reminded that the most obvious injuries may not pose the greatest threat to life. This process constitutes the ABCDE of trauma care.

- **A** – Airway maintenance with cervical spine protection;
- **B** – Breathing and ventilation;
- **C** – Circulation with hemorrhage control;
- **D** – Disability: neurologic status;
- **E** – Exposure/Environmental control: completely undress patient but prevent hypothermia.

The primary survey is a fluid yet systematic process. Each system is evaluated and resuscitation initiated simultaneously. The patient's airway is evaluated and protected before moving forward to assess breathing, circulation, and disability. Re-evaluation is another vital component of the primary survey. As the examiner moves through the primary survey he will constantly return to A – Airway to confirm an intact airway or to initiate an intervention should the airway status deteriorate. In this way the primary

Fig. 38.1 Trauma resuscitation – primary survey being completed by central doctor (yellow). Trauma team placing monitors, establishing intravenous access, disrobing patient.

survey is completed multiple times during the course of a trauma evaluation. Serial examination ensures that a system deterioration will be quickly detected and addressed.

Airway

The primary survey begins with an evaluation of the patient's airway while providing cervical spine protection. In the conscious, awake, and cooperative patient with a normal mental status and no distracting injuries this evaluation is easy and rapid. If the patient is speaking and the mental status is not altered (either from injury or drugs/alcohol) the airway is generally safe. In the same patient if there is no tenderness at the posterior midline of the cervical spine, the neck has normal range of motion without pain, and there are no focal neurological deficits, the cervical spine may be cleared clinically without further work-up.

In the obtunded or uncooperative patient airway evaluation can be challenging. The initial assessment should search for current or impending obstruction. The oral cavity should be suctioned and any foreign material removed. Facial fractures and tracheal injuries should be recognized as potential sources of airway obstruction. Facial and neck soft tissue injuries and burns can also progress to airway compromise (Fig. 38.2). Cervical spine injury should be assumed until it can be definitively ruled out. Initial measures to establish an airway (chin lift, jaw thrust) should be initiated while protecting the cervical spine. Protection of the cervical spine with an immobilization device (c-collar) should be initiated and maintained. Intervention with the establishment of a definitive airway should be a priority early in the resuscitation process. Indications for intubation can be separated into several broad categories:

- **inability to ventilate** – airway obstruction, chest trauma, paralysis, respiratory fatigue;
- **inability to oxygenate** – inhalation injury, acute respiratory distress syndrome (ARDS), pulmonary edema;

Fig. 38.2 (a) Facial gunshot wound with relatively small entrance site. Patient conscious but unable to move arms or legs. (b) Shattered anterior mandible with large oral laceration and hemorrhage, and extensive floor-of-mouth and tongue swelling. (c) CT scan with three-dimensional reconstruction demonstrating comminuted anterior mandibular fracture. (d) CT scan with coronal reconstruction demonstrating bullet in spinal canal at level of C5–C6 vertebrae. (e) CT with sagittal reconstruction demonstrating bullet in spinal canal at level of C5–C6 vertebrae.

- **airway protection** – unconsciousness, altered mental status, facial or head trauma, oral bleeding, aspiration risk (vomiting).

Once the airway has been evaluated and either cleared or definitively secured the practitioner will progress through the remainder of the primary survey. Patients that have been intubated should have a chest radiograph to confirm endotracheal tube position as soon as is reasonably possible. In addition to the anteroposterior (AP) chest film, a lateral cervical spine radiograph may be completed during the primary survey. A positive finding on the lateral film provides useful information. An absence of findings on the lateral film does not definitively rule out injury and the patient should remain in cervical spine protection until injury has been definitively ruled out. Patients at risk for cervical spine injury that cannot be cleared clinically should undergo a complete radiographic evaluation during the secondary survey. A complete plain film series would include an AP, lateral, odontoid view, and right and left oblique views. Computed tomography (CT) is recommended if plain films are

inadequate and in those patients with suspected cervical spine injury and head trauma. For a more detailed description of radiographic methods the reader is referred to Chapter 2.

Breathing

After a definitive airway is confirmed the patient's breathing is evaluated. The chest wall should be exposed to allow for a thorough inspection. Inspection will confirm appropriate chest movement with respiration. Areas of blunt trauma, penetrating injuries, open chest wounds, or flail segments (multiple rib fractures) are quickly identified. The lungs should be auscultated in all fields to confirm normal air movement. Palpation and percussion will confirm diaphragmatic excursion and may detect signs of blood or air in the pleural space.

Diminished or absent breath sounds may indicate a pneumothorax or hemothorax (separation of the visceral and parietal pleura with entry of air or blood into the pleural space). A small pneumothorax may go undetected during the primary survey and be rec-

ognized and treated during the secondary survey. A tension pneumothorax develops if, after chest wall or lung injury, a one-way valve mechanism exists that allows air to enter the pleural space without exit. With each respiratory cycle more air is drawn into the pleural space (Fig. 38.3). There is an eventual shift in the mediastinum to the contralateral side and compression of the major vessels entering the chest. With compression there is a decrease in venous return to the heart and resulting decline in cardiac output. This lesion is suspected in the patient with signs of chest trauma, absence of breath sounds on one side, hyperresonance of the chest wall, hypotension, and shift of the trachea to the contralateral side. The treatment is immediate decompression of the pleural space with a large-bore needle inserted through the second intercostal space along the mid-clavicular line, followed by the formal insertion of a thoracostomy tube.¹¹

Intubation and positive pressure ventilation can cause a relatively small pneumothorax to expand rapidly. Breathing should be repeatedly evaluated with auscultation of the chest and a chest radiograph should be obtained as soon as possible.

It is not uncommon for patients with chest trauma to have some degree of intrathoracic hemorrhage. Intrathoracic bleeding may be caused by disruption of a large central vascular structure, laceration of a systemic artery (internal mammary or intercostal), or from a lung parenchymal lesion. Enough blood can collect in the chest cavity to cause hypovolemic shock. Massive hemothorax should be suspected in trauma patients with chest trauma, diminished breath sounds, and signs of shock. Immediate thoracostomy tube placement allows for decompression of the lung parenchyma and monitoring of ongoing blood loss. A large volume (2000 ml) of blood may drain immediately and continue at rates of 100–200 ml/hour. Small lesions generally resolve spontaneously after chest tube placement and lung re-expansion. Persistent bleeding may require interventional or surgical repair.¹²

Circulation

Bleeding and hypovolemic shock account for 30–40% of trauma mortality. The volume status of a patient with multiple injuries needs to be rapidly evaluated and aggressively managed. The initial assessment begins immediately. A quick evaluation of the patient's level of consciousness, skin color, and pulses can be completed while monitors are being placed and intravenous access established. This information can help identify those patients in jeopardy of hypovolemic shock even before the blood pressure is first measured. When circulating blood volume is decreased cerebral perfusion may be critically impaired, resulting in altered levels of consciousness. Warm pink skin with rapid capillary refill is generally associated with the euvoletic patient. In contrast the patient with cold, clammy skin that appears ashen grey may be severely hypovolemic. Palpation of peripheral and central pulses can give a fast estimate of systolic blood pressure. Classically a palpable carotid pulse correlates with a systolic blood pressure of at least 60 mmHg, a palpable femoral pulse correlates with a systolic pressure of at least 60–70 mmHg, and a palpable radial pulse correlates to a systolic blood pressure of at least 80 mmHg. There has been some debate about the accuracy of these estimates.¹³ The general principle remains; full, slow, and regular peripheral pulses are generally associated with a normal circulating blood volume. A rapid, thready pulse is usually a sign of hypovolemia. Absent central pulses signify the need for immediate resuscitation.

Hemorrhage is defined as an acute loss of circulating blood volume. The average adult blood volume is approximately 7% of body weight (70 ml/kg). For a 70 kg adult the estimated blood volume is approximately 5 l. Children have estimated blood volumes of 8–9% of body weight and infants' estimated blood volumes are 9–10% of body weight. For the obese

Fig. 38.3 (a) Small left pneumothorax with partial collapse of left lung (line) and air between the lung and the chest wall (pleural space). Also note multiple rib fractures on the left side. (b) Left tension pneumothorax with displacement of heart and trachea to the right side.

patient estimates of blood volume should be based upon ideal weight and not the patient's actual weight. Blood loss of 10–15% of a healthy person's blood volume can generally be tolerated without clinical sequelae. Blood donation typically takes 8–10% of a donor's blood volume.

There are multiple potential sources of bleeding in the trauma patient. External blood loss is managed during the primary survey with pressure on the wound. Large volumes of blood loss may occur with hemorrhage into the chest or abdomen. There may also be extensive bleeding associated with fractures of the pelvis or long bones.

Shock is defined as an abnormality in the circulatory system that results in inadequate tissue perfusion and oxygenation. Early signs of a collapsing circulatory system are tachycardia and peripheral vasoconstriction. As the system continues to fail, perfusion to central organs and muscle will decrease in order to preserve cerebral perfusion. Shock in the trauma patient is most likely caused by acute blood loss. Other categories of shock include cardiogenic, septic, and neurogenic.¹⁴

Classifications of hemorrhage were developed to help recognition of the early signs of hypovolemic shock and to guide volume replacement. Hypotension resulting from acute blood loss occurs relatively late. Early signs of hypovolemic shock include tachycardia and decreased peripheral perfusion. Classes of hemorrhage are defined by blood loss (volume and percentage) and the resulting physiologic responses (blood pressure, heart rate, respiratory rate, urine output, and mental status).

- Class 1 hemorrhage is less than 750 ml or less than 15% of estimated blood volume. Physiologic parameters are normal. Heart rate is less than 100 beats per minute. Blood pressure and respiratory rates are normal. Urine output is greater than 30 ml/hour. The patient may be slightly anxious but mental status is otherwise normal.
- Class 2 hemorrhage is 750–1500 ml or 15–30% of estimated blood volume. These patients will have a drop in blood pressure with a resulting tachycardia (greater than 100 beats per minute). They will also show a decline in urine output (20–30 ml/hour) and an increased respiratory rate (20–30 breaths per minute). These patients may show moderate anxiety.
- Class 3 hemorrhage is 1500–2000 ml or 30–40% of estimated blood volume. These patients are tachycardic (greater than 120 beats per minute), hypotensive, and tachypneic (30–40 breaths per minute). Urine output continues to decline (5–15 ml/hour). Confusion may be an early sign of decreased cerebral perfusion.
- Class 4 hemorrhage (greater than 2000 ml or 40% of estimated blood volume) is immediately life threatening. Symptoms include marked tachycardia (greater than 140 beats per minute), tachypnea

(greater than 35 breaths per minute), and a significant decrease in systolic blood pressure. Urine output is negligible and patients are confused or lethargic.

The diagnosis and management of shock occurs rapidly during the primary survey. Access to the vascular system is critical. Initial vascular access is obtained with two large-bore (16 gauge or larger) peripheral intravenous catheters. If peripheral access is inadequate or not readily obtainable, central venous access may be established through the jugular, subclavian, or femoral veins. With initial intravenous access, samples may be sent and blood typed and cross-matched for possible transfusion.

Resuscitation of hemorrhagic shock begins with the administration of 2 l of crystalloid solution (normal saline, lactated Ringer's solution). Further fluid resuscitation and the need to transfuse blood are based upon estimates of the volume of blood loss and the patient's response to the initial fluid bolus. If the patient had minimal blood loss (10–15% of estimated blood volume) and a rapid response to the initial fluid with a return to normal vital parameters they are not likely to require blood transfusion. If the patients had moderate blood loss (20–40% of estimated blood volume) and only a transient response to the initial fluid bolus then ongoing fluid resuscitation is anticipated. It is likely that the patient will require blood transfusion but type-specific blood may be available. In the patient with severe hemorrhage (over 40% of estimated blood volume) immediate transfusion is required. In this situation type O blood will be used until type-specific blood is available.¹⁵

Urinary catheters and arterial lines may be placed during the primary survey and both provide valuable information on the circulatory status. Urine output is a sensitive indicator of volume status and reflects renal perfusion. Urinary catheters are contraindicated in patients in whom a urethral injury is suspected. Urethral injury should be suspected with blood at the penile meatus, perineal ecchymosis, blood in the scrotum, or pelvic fracture. An arterial catheter provides immediate monitoring of the patient's blood pressure. It also provides access for repeated laboratory samples.

Disability (neurologic evaluation)

The primary survey concludes with a rapid neurologic evaluation. A decline in the patient's level of consciousness may be due to a decrease in cerebral perfusion or cerebral oxygenation, or may be due to an intracranial injury. The first response to an altered mental status is to re-evaluate airway, breathing, and circulation. A rapid neurologic assessment should include an evaluation of sensory and motor function and rectal tone. Other potential causes of an acute decline in level of consciousness are hypoglycemia and alcohol or drug intoxication. Traumatic brain

injury should remain high on the differential list until proven otherwise.

The Glasgow Coma Scale (Table 38.1) is a rapid objective clinical measure of neurologic function. The scale was initially published by two neurosurgeons

Table 38.1 Glasgow Coma Scale (GCS).

Eye opening
Spontaneous – 4
To speech – 3
To pain – 2
None – 1
Motor response
Obeys commands – 6
Localizes to pain – 5
Normal flexion (withdrawal) – 4
Abnormal flexion (decorticate) – 3
Abnormal extension (decerebrate) – 2
Flaccid – 1
Verbal response
Oriented – 5
Confused conversation – 4
Inappropriate words – 3
Incomprehensible sounds – 2
None – 1

(Graham Teasdale and Bryan Jennett) at the University of Glasgow. The scale assesses eye opening, motor response, and verbal response. Each category is scored based upon best response and the scores are tallied to determine a Coma Score. The highest score obtainable is 15 (indicating an unaltered, awake patient) and the lowest is 3 (indicating deep coma).¹⁶

Head trauma and coma can be graded based upon the Glasgow Coma Score. Scores of 14–15 are considered mild, 9–13 moderate, and 3–8 severe. The patient's Glasgow Coma Score along with mechanism of injury (blunt versus penetrating) and type of head trauma (skull fracture, intracranial lesion) are used to triage the patient's neurologic injuries.

Multiple types of injuries are possible after head trauma. Scalp lacerations and skull fractures may be identified during the primary survey (Fig. 38.4). Intracranial lesions include epidural and subdural bleeding, intracerebral bleeding, contusion, concussion, and diffuse hypoxic injury.

Skull fractures may occur along the convexity of the cranial vault (more common) or at the cranial base (Fig. 38.5). Fractures may be linear, complex, comminuted, or depressed. Linear fractures of the skull convexity are most commonly seen in the trauma patient. Open or depressed fractures may be diagnosed clinically. Closed, non-depressed fractures may require

Fig. 38.4 (a) Large scalp laceration stapled in the emergency department to control hemorrhage. (b–d) CT scans demonstrating sagittal fracture of the cranial vault. (e) Skull fracture at time of craniotomy for bleeding.

CT for diagnosis. Fractures of the skull base are much less commonly seen in the trauma patient (4% of skull fractures). Skull base fractures are difficult to diagnose clinically but may be suspected in the patient with periorbital ecchymosis (raccoon eyes), mastoid ecchymosis (battle sign), cerebral spinal fluid rhinorrhea/otorrhea, or blood behind the tympanic membrane. Skull fractures increase the likelihood of a subdural or epidural hematoma. They also provide a pathway for the entry of bacteria or air (pneumocephalus).¹⁷

Hemorrhage may occur beneath the dura (subdural) or between the dura and skull (epidural); each has characteristic clinical and radiographic features. Epidural hematomas occur in up to 10% of patients with severe head trauma. They typically evolve rapidly. Many of these patients are unconscious when first seen but may have a "lucid" interval of minutes to hours before coma develops. These hematomas are located between the skull and dura and are lenticular in shape. They are most often seen in the temporal or temporoparietal region and usually result from a tear of the middle meningeal artery. The high pressure arterial bleeding of an epidural hematoma can lead to irreversible brain injury and death within hours. Rapid surgical evacuation and ligation of the damaged vessel is indicated.

Subdural hematomas are more common than epidural hematomas. They are caused by tearing of veins traversing the dura and result in blood collecting between the dura mater and the arachnoid. Blood collects more slowly in subdural hematomas but the underlying brain injury is typically much more severe than that with epidural hematomas. On imaging studies subdural hematomas appear as crescentic collections over the convexity of one or both hemispheres (Fig. 38.6). Blood tends to conform to the contour of the underlying cerebral cortex. These are more com-

monly seen in the frontotemporal region. Patients, if conscious, may present with a unilateral headache and slightly enlarged pupil. Coma, hemiparesis, and pupillary asymmetries are associated with larger hematomas. In rapidly deteriorating patients hematoma evacuation may be required. In smaller lesions no intervention may be necessary.¹⁸

The skull is a rigid container and contains brain parenchyma, fluid (interstitial and cerebrospinal), and blood (arterial and venous). The expansion of any of these compartments (e.g. edema) or the addition of a space-occupying process (e.g. hematoma) can lead to an elevation of the intracranial pressure. As intracranial pressure begins to rise above normal (15 mmHg) a progression of neurologic abnormalities will develop. Effects on the cerebral cortex will produce a decline in level of consciousness. Effects on the mid-brain will produce fixed, dilated pupils. Effects on the pons will result in loss of corneal reflex. Effects on the medulla will result in apnea, hypotension, and death.¹⁹

During the primary survey, once airway, breathing, and circulation are established and stabilized, the focus becomes preservation of cerebral function. Patients with physical findings suggestive of an intracranial process (unequal pupils, asymmetric motor exam) should undergo an immediate head CT scan. Patients with less severe head trauma who are otherwise stable but have symptoms of headache, vomiting, drug or alcohol intoxication, persistent amnesia, or seizures should also have a head CT scan while in the emergency department.²⁰

Exposure/environmental control

The primary survey concludes with complete exposure of the patient. The patient should be undressed to allow for a complete head to toe physical examination. During the resuscitation, and particularly once the patient is undressed, it is critical to protect the patient from developing hypothermia. Hypothermia develops in up to 70% of trauma patients at some point during resuscitation. Exposure, paralysis, and fluid administration all contribute to lowering the patient's core temperature. Hypothermia can produce

Fig. 38.5 (a) CT scan demonstrating a frontal epidural hematoma. Collection of blood between skull and dura producing characteristic lenticular shape on CT. (b) CT scan seen in (a) now with bone windows showing skull fracture causing epidural hematoma. (c) CT scan demonstrating parietal epidural hematoma.

Fig. 38.6 CT scan demonstrating a subdural hematoma. Blood between the dura and brain with irregular borders and causing an obvious mass effect on the brain tissue with loss of ventricle and shift of midline structures.

Fig. 38.7 (a, b) Plain radiographs demonstrating radial and ulnar fractures mid-diaphysis. (c, d) Plain radiographs demonstrating comminuted, displaced distal femur fracture.

a relative coagulopathy. It alters platelet function, the coagulation cascade, and the fibrinolytic system. A drop in the core temperature of just a few degrees is enough to produce a marked decrease in clotting ability. Hypothermia also produces a dramatic increase in oxygen consumption. Studies have shown that a decrease in the core temperature of 0.3°C produces a 7% increase in oxygen consumption and a decrease of 1.2°C produces a 92% increase in oxygen consumption. Shivering has been shown to increase oxygen consumption by 400%. Hypothermia can produce negative inotropic changes in the heart and respiratory depression, and exacerbate hyperglycemia by decreasing insulin production and creating end-organ insulin resistance. Heaters, forced air warming devices, and administering warmed fluids should be started early during the evaluation of trauma patients.²¹

Secondary survey

The secondary survey is a complete history and head to toe physical examination of the patient. This is not initiated until the primary survey is complete and the patient is relatively stable. The secondary survey is an incredibly important part of the overall trauma evaluation. The reported incidence of missed injuries in the trauma patient ranges from 8–60%. Studies have shown that practitioners are most likely to miss injuries in the most critically injured patients.²² A large proportion of missed injuries involve orthopedic injuries, including fractures in the upper and lower extremities. Some centers now advocate a tertiary survey to be completed while the patient is in hospital as a failsafe method of identifying potentially missed injuries.

The secondary survey begins with a more detailed patient history. Details of the current injury are

Fig. 38.8 Plain radiograph demonstrating pelvic fracture with wide diastasis of the pubis with widening of the sacroiliac joints.

obtained from the patient, family, or other witnesses. A full medical history including medical conditions, medications, drug allergies, and tobacco, alcohol, and substance abuse are also obtained.

The physical examination begins with a re-evaluation of the patient's vital signs. If the patient's vital signs are worsening or if there is a deterioration of any system evaluated during the primary survey, the secondary survey is halted and resuscitation is continued.

A brief neurological examination is completed and should include a recalculation of the Glasgow Coma Score. Cranial nerves are evaluated with particular attention on the pupillary exam. Motor and sensory examinations of the upper and lower extremities are completed bilaterally. Deep tendon reflexes are also evaluated in upper and lower extremities. Focal abnormalities in the exam should alert the examiner to potential brain or spine injuries.

Next a full maxillofacial examination is completed. The scalp, facial skeleton, eyes, ears, nose, and oral cavity are evaluated. Visual acuity is assessed and fundoscopic and otoscopic exams are completed. The neck is evaluated for cervical spine trauma, penetrating injuries, and evidence of carotid injury.

Penetrating neck injuries are often characterized by the anatomic zone of the neck involved. Zone one is bound by the thoracic inlet inferiorly and the cricoid cartilage superiorly. Structures at greatest risk in this zone are the subclavian vessels, brachiocephalic veins, common carotid arteries, aortic arch, jugular veins, trachea, esophagus, lung apices, cervical spine, spinal cord, and cervical nerve roots. Zone two is bound by the cricoid cartilage inferiorly and the inferior border of the mandible superiorly. Important structures in this region include the carotid and vertebral arteries, jugular veins, pharynx, larynx, trachea, esophagus, and cervical spine and spinal cord. Zone three is from the inferior border of the mandible to the base of the skull. Penetrating injuries superficial to the platysma muscle may require little more than a simple closure. Penetrating injuries deep to the platysma may cause acutely life-threatening injuries or may harbor occult injuries that can progress to life-threatening over time if not diagnosed. Potential work-up could include neck exploration, angiography, CT, esophagoscopy, and bronchoscopy.²³

The chest is evaluated next and should undergo inspection, palpation, percussion, and auscultation. The chest wall should be evaluated front and back for signs of trauma. The ribs, clavicles, sternum, and thoracic and lumbar spine should be palpated. Areas of pain on palpation should be evaluated for fracture. Percussion and auscultation will confirm normal air flow.

Next the abdomen is evaluated. The abdomen should be inspected for signs of trauma including seat belt marks, ecchymosis, and penetrating injuries. Palpation of a soft non-tender abdomen in a neurologically intact patient without other distracting injuries and without intoxication may be followed without further work-up. An abnormal (tense or tender) or unreliable (unconscious, intoxicated or altered) exam should be followed by CT scans with both intravenous and intragastric contrast or by an ultrasound evaluation. An unstable patient with a high clinical suspicion for an abdominal injury may proceed straight to the operating room for an exploratory laparotomy.

The FAST exam (focused assessment with sonography in trauma) is used to identify free fluid (usually blood) in the peritoneal, pericardial, and pleural spaces. FAST scans attempt to identify free fluid in four regions: right upper quadrant (abdomen), left upper quadrant (abdomen), behind the bladder in the pelvis, and in the pericardial space. It is not as accurate as CT at diagnosing abdominal injuries. It is most helpful in evaluating the abdomen and pericardial

space in the unstable patient or in those who could be observed without CT. It remains an accurate evaluation that can be completed rapidly and repeated, and does not require a radiologist or technician. The exam is portable and can be completed bedside in the emergency room or hospital ward. The ultrasonography provides limited information about solid organ injury, the retroperitoneum or the diaphragm.²⁴ It has also been shown to have decreasing accuracy in patients with pelvic fractures.²⁵

The physical examination should continue with an examination of the extremities, pelvis, and genitourinary system. Obvious deformities of the long bones warrant radiographic and orthopedic evaluation. Ecchymosis and edema should also alert the examiner to possible underlying fractures. Peripheral pulses should be evaluated. Abnormalities in peripheral pulses should be evaluated for vascular injury. The pelvis is examined for any deformity and palpated for instability and pain. Pelvic fractures should be suspected when there is ecchymosis over the iliac wings, pubis, labia, or scrotum. The anterior posterior pelvis film is a useful initial screen for pelvic fractures and can be completed in the emergency department.

The perineum should be examined for contusions, lacerations, and urethral bleeding. A rectal examination should be completed to assess rectal tone, prostate position, rectal blood, and the integrity of the rectal wall. Female patients should also undergo a vaginal examination looking for blood and vaginal wall injuries. Female patients should also have a pregnancy test completed.

Serial and repeated examination and evaluation are hallmarks of the trauma evaluation. It is well documented that an initial secondary survey is inadequate in many critically injured patients. The concept of a tertiary examination developed in the early 1990s. The idea was that the trauma patient should be re-evaluated early in the course of hospitalization with the intention of looking for missed injuries. A complete and thorough head to toe physical examination is completed. All radiographic studies should be reviewed by a radiologist.

Conclusion

In recent decades there have been many advances in trauma care. Patients are resuscitated rapidly and are now surviving injuries that would have been fatal in the past. Oral and maxillofacial surgeons undergo education and training and oral and maxillofacial surgery residents now participate in Advanced Trauma Life Support courses. Oral and maxillofacial surgeons will always be involved with the early evaluation and treatment of patients with facial trauma. Having an understanding of the complexity of trauma care and the details of an appropriate trauma evaluation will improve patient outcomes.

Chapter 39

Traumatic Dental Injuries

Lars Andersson and Jens O. Andreasen

Traumatic dental injuries (TDI) are the most common of the oral injuries. The prognosis for some TDI depends very much on correct early emergency management at the place of accident and at the clinic. This chapter presents how to diagnose, classify, and treat TDI with emphasis on the emergency phase. An overview of pulpal and periodontal healing and complications after TDI is also given.

Summary, 816

somatic injuries, are most frequently seen at ages 15–25 years and occur throughout life (Fig 39.1).^{1,3}

In a study of patients presenting with traumatic oral injuries in Sweden, traumatic dental injuries (TDI) were the most common oral injury (92%), followed by orofacial soft tissue injuries (28%), whereas fractures of the maxillofacial bones were relatively rare and seen in only 6% of such patients.¹ Most studies report an annual incidence of TDI at 1–2% of the population.^{2–4} The prevalence is high and every fourth boy and every fifth girl have already sustained dental injuries at the age of 14.⁵ A study in the UK showed that one in five children has sustained a TDI to the permanent teeth before leaving school.⁶ A comprehensive national survey in the USA showed that one in four adults had evidence of TDI.⁷ Due to the high number of injured individuals and often complex treatment, TDI are associated with high costs for society and the individual.^{8–10}

The prognosis of treatment for some dental injuries, especially avulsed teeth, depends very much on early and correct management at the place of the accident and during emergency treatment at the clinic.^{2,11–16}

Examination and diagnosis of dental injuries

History taking is important with regard to when, where, and how the injury occurred, as well as the patient's general health and possible medication. Be alert to other injuries and symptoms indicating more serious injuries. See Chapter 38 regarding assessment of the injured patient. It is also of value to ask what has been done before the patient reached the clinic, such as any treatment carried out elsewhere and how avulsed teeth have been stored.

A brief summary is given here of the important issues for emergency examination and for TDI. For a more detailed description the reader is referred to recent textbooks and manuals on the subject.^{2,16} As for oral and maxillofacial injuries, it is important to

Epidemiology of traumatic dental injuries and relation to oral and somatic injuries

Oral injuries (dental, soft tissue, and bone) caused by trauma occur frequently. They are most common during the first 12 years of life and are rare after the age of 30.^{1–3} In contrast, other injuries to the body,

Fig. 39.1 Incidence per 100 inhabitants per year for oral and non-oral injuries. From Andreasen *et al.* 2007.²

examine and treat TDI in a systematic way. Examine from the outside towards the inside and treat from the inside towards the outside is a helpful principle for a systematic approach for examining oral injuries. Suturing of lips should ideally be carried out after intraoral emergency examination and treatment has been performed, otherwise it may be difficult to enter the oral cavity once edema has started to develop.

The possibility of inhaling or swallowing teeth at the time of injury should always be considered when teeth, parts of the teeth or prosthetic appliances are missing. This is especially important in the unconscious patient; if there is reason to suspect inhalation or swallowing of a tooth or dental appliance, it is important that radiographs of the chest and the abdomen be considered. Inhalation of foreign bodies is normally associated with symptoms such as coughing but may also occur in a conscious patient without producing symptoms.

Examination of crowns of teeth should be carried out in order to look for presence and extent of fractures and pulp exposures. Crown–root fractures in the molar and premolar regions should be expected when there has been an indirect trauma such as a blow to the chin. Crown–root fractures in one quadrant are very often accompanied by similar fractures on the same side of the opposing jaw. For this reason it is therefore necessary to examine occlusal fissures of all molars and premolars to detect possible fractures (Fig. 39.2).

Fig. 39.2 Induced dental trauma. (a) Impact was transferred via the chin to the dental arches. (b) Crown–root fractures were inflicted in both right premolars by the forceful occlusion. From Andreasen *et al.* 2007.²

The fracture surface should be carefully examined for the extent of fracture in dentin and pulp exposures (Fig. 39.3). When pulp is exposed, the size and location should be recorded. In some cases, the dentin layer may be so thin that the outline of the pulp can be seen through the dentin wall. One should take care

Fig. 39.3 Right central incisor with crown fracture of dentin showing pulpal exposure.

not to perforate the thin dentinal layer during the examination.

Displacement and avulsion of teeth are usually evident by visual examination; however, minor abnormalities can often be difficult to detect. In such cases, it is helpful to examine the occlusion as well as radiographs taken at various angulations. In cases of tooth luxation, the direction of the dislocation as well as extent should be recorded. It is important to remember that, apart from displacement and interference with occlusion, laterally luxated and intruded teeth present very few clinical symptoms (Fig. 39.4). Moreover, these teeth are normally firmly locked in their displaced position and do not usually demonstrate tenderness to percussion. While radiographs can be of assistance, diagnosis is confirmed by the percussion tone, when tapping on the tooth with the handle of an instrument. A high, bony percussion tone is registered compared to the normal sound of uninjured teeth. When a Le Fort I fracture is present a change in percussion sound to a cracked-like sound can be noticed.

In the primary dentition, it is of utmost importance to diagnose the direction of dislocation of the apex of a displaced primary tooth, since this tooth is located in close relationship to the permanent successors and can impinge on the development of the permanent

Fig. 39.4 Intruded incisors. The teeth are impacted and locked in the bone and show no signs of tenderness to percussion. A high, bony percussion sound is registered.

successor (Fig. 39.5). This diagnosis is often best done by palpating the alveolar process from a vestibular approach.

The patient may also react with pain to percussion of a tooth which is indicative of damage to the periodontal ligament. As with all examination techniques used at the time of injury, the percussion test should be started on a non-injured tooth to ensure a reliable patient response. In smaller children, the use of a fingertip can be a gentler diagnostic tool.

Patients can usually detect and guide the examiner to the place where there has been a change in the occlusion. Abnormalities in occlusion can indicate fractures of the jaw or alveolar process or a lateral luxation (Figs 39.6–39.8). All teeth should be tested for abnormal mobility, both horizontally and axially. It should be remembered that erupting teeth and primary teeth undergoing physiologic root resorption always exhibit some mobility. The typical sign of alveolar fracture is movement of adjacent teeth when the mobility of a single tooth is tested (Fig. 39.6). Palpation of the alveolar process is important for detection of fractures with dislocations.

When mobility of a tooth is detected it is not possible to discriminate between luxation injuries and root fractures without radiographic examination (Figs 39.9 and 39.10). The site of the root fracture will have an influence on the degree of mobility.

Pulp testing following traumatic injuries is a controversial issue. These procedures require cooperation and a relaxed patient, in order to avoid false reactions. However, this is often not possible during initial treatment of injured patients, especially children. The interpretation of pulpal sensibility tests performed immediately after traumatic injuries is complicated by the fact that sensitivity responses can be temporarily or permanently decreased, especially after luxation injuries. However, repeated testing has shown that normal reactions can return after a few weeks or months. Moreover, teeth which have been loosened can elicit pain responses merely from pressure of the pulp testing instrument. It is therefore

Fig. 39.5 (a) Anatomic relationship between primary incisor and its permanent successor in a human skull. (b) Histologic relationship between primary incisor and its permanent successor. From Andreasen *et al.* 2007.²

Fig. 39.10 Radiograph showing fractures of the roots 11 and 21.

important to reposition and immobilize such teeth, e.g. root-fractured or extruded incisors, prior to pulp testing. Another important factor to consider when testing the pulp is the stage of eruption; teeth under root development sometimes show an unreliable response. Teeth undergoing orthodontic movement display higher excitation thresholds. If local anesthetics are to be administered for various treatment procedures, pulp testing should be performed prior to doing this. Pulpal sensibility testing is difficult in the emergency situation but it is helpful, as such tests have a strong predictive value for later pulp healing complications. For this reason it is important to carry out a sensibility test within the first week after trauma to establish a point of reference for evaluating pulpal status at later follow-up examinations.

Radiographic examination of TDI

This is an overview of suitable examinations for patients who have been subjected to dentoalveolar trauma. For more details of radiographic examination the reader is referred to Chapter 2 in this book.

Dental films

All injured teeth should be examined radiographically to diagnose injuries and to reveal the stage of root formation which is important for the choice of treatment method. The ideal method is the use of different angulations for each traumatized tooth, using a standardized projection technique. Thus, a traumatized anterior region of the maxilla is covered by one occlusal film, projected steeply superiorly, and three periapical exposures perpendicular to the long axes of the teeth, where the central beam is directed between the central incisors and for each lateral incisor. This procedure ensures diagnosis of even minor dislocations or root fractures. It is important to bear in mind that a steep occlusal exposure is of special value in the diagnosis of root fractures and lateral luxations with oral displacement of the crown.

Most root fractures are disclosed by radiographic examination provided that they are steeply superiorly projected. A widening of the periodontal space is seen in lateral and extrusive luxations, whereas intruded teeth often demonstrate a lack of periodontal space.

Extraoral radiographs may be of value for determining the direction of dislocation of intruded primary incisors. Dislocated tooth fragments within a lip laceration can be demonstrated radiographically by the use of an ordinary film placed between the dental arches and the lips (Fig. 39.11). A short exposure time is advocated for this situation.

Panoramic technique

This method gives an excellent overview of the dentoalveolar region. It is especially useful in cases where a jaw fracture is suspected.

Fig. 39.11 Radiograph of a lacerated lip showing coronal fragment of a fractured incisor.

Conventional computed tomography scanning

This is a very useful method in the diagnosis of maxillofacial fractures; however, the resolution is not optimal and radiation exposure is too high to make it useful for dental trauma diagnosis.

Micro computed tomography scanning, cone-beam computed tomography

Conventional dental and panoramic images have limited diagnostic ability due to their two-dimensional character. Resolution in computed tomography (CT) scans is not high enough to be useful for diagnosis in dental trauma. Cone-beam CT has high enough resolution to be a valuable tool for diagnosis of different dental injuries (Fig. 39.12). For more information regarding cone-beam CT see Chapter 2.

Classification and clinical findings

TDI can be classified in many ways but the following system based on World Health Organization classification, modified by Andreasen,^{2,17} is well suited to the clinical situation; following this system facilitates treatment.

Injuries to the hard dental tissues and the pulp

A schematic overview of hard tissue injuries is presented in Fig. 39.13.

Fig. 39.12 Cone-beam CT picture of a central incisor showing a lateral luxation with fracture of the labial bone plate. From Andreasen *et al.* 2007.²

Crown infraction

This is incomplete fracture of the enamel without loss of tooth substance (Fig. 39.13a mesial). Various patterns of craze lines can be detected depending on the location and direction of trauma, e.g. vertical, horizontal, or oblique lines.

Uncomplicated crown fracture

This is a fracture with loss of tooth substance (Fig. 39.13a distal, Fig. 39.13b). It involves enamel or enamel and dentin without pulp exposure. The exposed dentin usually gives rise to symptoms such as sensitivity to hot and cold stimuli and mastication.

Fig. 39.13 Injuries to the hard dental tissues and pulp. (a) Crown infraction and uncomplicated fracture without involvement of dentin. (b) Uncomplicated crown fracture with involvement of dentin. (c) Complicated crown fracture. (d) Uncomplicated crown-root fracture. (e) Complicated crown-root fracture. (f) Root fracture. From Andreasen *et al.* 2007.²

Complicated crown fracture

This is a fracture with loss of enamel and dentin with pulp exposure (Fig. 39.13c). The exposed pulp often gives rise to pain and sensitivity.

Uncomplicated crown–root fracture

This is a fracture of enamel, dentin, and root structure without pulp exposure (Fig. 39.13d).

Complicated crown–root fracture

This is a fracture of enamel, dentin, and root structure with pulp exposure (Fig. 39.13e). Vitality testing is usually positive. Even with pulp exposure, symptoms are usually few and limited to pain upon heat and cold exposure when touching the fragment or biting on the fragment.

Root fracture

This is a horizontal root fracture comprising dentin, cementum, and pulp (Fig. 39.13f). The fracture is located within the alveolus. The coronal fragment may be mobile and displaced. The tooth might be slightly extruded and tender to percussion.

Injuries to the periodontal tissues

A schematic overview of injuries to the periodontal tissues is presented in Fig. 39.14.

Concussion

This is an injury to the tooth-supporting structure without abnormal loosening or displacement of the tooth (Fig 39.14a). The tooth has not been displaced and does not have increased mobility. It is tender to touch or tapping.

Subluxation

Subluxation is injury to the tooth-supporting structure with abnormal loosening, but without displacement of the tooth (Fig 39.14b). The tooth is tender to touch or tapping and has increased mobility. There might be bleeding from the gingival sulcus.

Extrusive luxation (extrusion)

This is partial displacement of the tooth out of its socket (Fig 39.14c). The tooth appears elongated and is excessively mobile. There is bleeding from the gingival sulcus.

Lateral luxation

Displacement of the tooth occurs in a direction other than axially (Fig. 39.14d). The tooth is displaced in its

socket, most commonly with the crown in a retroclined position. The tooth is most often immobile due to its locked position in the socket and there is a high ankylotic percussion tone.

Intrusive luxation (intrusion)

The tooth has been displaced axially into the alveolar bone through the alveolar socket (Fig 39.14e). The crown appears shortened. There is usually bleeding from the gingiva. Percussion tone is high and metallic similar to that of an ankylosed tooth. The percussion tone can be used to distinguish an intruded tooth from a partially erupted or unerupted tooth.

Avulsion (exarticulation, total luxation)

This is complete displacement of the tooth out of its socket (Figs 39.14f and 39.15; see also Fig. 39.20). There is bleeding from the socket which is empty.

Treatment

The following treatment guidelines focus on what should be carried out in the emergency situation for permanent teeth.^{18,19} For more detailed information regarding treatment after the emergency situation see textbooks and articles^{2,3,13,20–25} and International Association of Dental Traumatology (IADT) guidelines,^{18,19} which are regularly updated on the Internet (www.iadt-dentaltrauma.org).

Infraction

No treatment is necessary. In cases of multiple craze lines, they might later be sealed with an unfilled resin to prevent future discoloration.

Crown fracture**Uncomplicated crown fracture**

- If the fracture is confined to enamel; a slight grinding or smoothing of sharp edges may be sufficient.
- With more extensive loss of enamel, a later composite restoration is necessary as recontouring is not sufficient.
- Fracture comprising dentin and enamel but the fragment is not found: the exposed dentin should be covered with glass ionomer as an emergency treatment. It is possible to make a permanent composite restoration using a bonding agent in the emergency situation, or this treatment can be performed at a later stage.
- Fracture comprising dentin and enamel and the fragment is found: the fragment can immediately or later be bonded to the tooth (Fig. 39.16). If it is decided to perform the bonding later it is impor-

Fig. 39.14 Injuries to the periodontal tissues. (a) Concussion. (b) Subluxation. (c) Extrusive luxation. (d) Lateral luxation. (e) Intrusive luxation. (f) Avulsion. From Andreasen *et al.* 2007.²

tant to cover the exposed dentin with a thin layer of, for example, glass ionomer cement. Save the fragment by keeping it moist in saline.

Fig. 39.15 Avulsed right central and lateral incisor.

Complicated crown fracture

Exposed vital pulp

Open root apex

In young patients with immature, still developing roots it is very important to preserve pulp vitality by pulpotomy; this technique-sensitive procedure can be performed later, when optimal facilities are available. In the emergency phase pulp capping with calcium hydroxide can be performed.

Pulpotomy is performed by removal of 1–2 mm of the exposed pulp tissue below the exposure site. The pulp is removed using a sterile round diamond bur in a high-speed hand piece then irrigated with sterile saline. After hemostasis, $\text{Ca}(\text{OH})_2$ or white mineral trioxide aggregate (MTA) can be applied. A thin layer of glass ionomer is placed to achieve a tight seal. Composite restoration can be performed either in the emergency phase or later. If the crown fragment is available, bonding of the crown fragment to the tooth can be performed.

Fig. 39.16 (a) Crown fractured right central incisor. (b) Tooth fragment found. (c) Fragment bonded back to its original position using a dentin-bonding technique.

Closed root apex

In young patients when crown substance loss is not too extensive, pulp capping or pulpotomy can be performed. If there is severe loss of crown substance or if too much time has elapsed between the injury and treatment, pulp extirpation is carried out and $\text{Ca}(\text{OH})_2$ placed to save the tooth in the emergency phase. Root canal treatment is carried out later.

Necrotic pulp**Open root apex**

An apexification procedure is performed using $\text{Ca}(\text{OH})_2$ paste or a root-end closure procedure is performed using MTA. Follow-up is important.

Closed root apex

Canal debridement is carried out and $\text{Ca}(\text{OH})_2$ is applied; root canal treatment is completed within 2 weeks.

Crown-root fracture**Uncomplicated crown-root fracture**

Removal of the coronal fragment for careful inspection of the fracture level is necessary in order to take a final decision on whether restoration is possible for the remaining fragment. This can be done in the emergency phase. An alternative in the emergency phase, is to stabilize the coronal fragment to the tooth by bonding. The definitive treatment depends on the extent of the fracture.

To restore the tooth, gingivectomy, ostectomy, or orthodontic extrusion may later be required. Surgical extrusion is not recommended because of risk of devitalizing the pulp. If post space is required, elective root canal treatment should be carried out.

Complicated crown-root fracture

Removal of the coronal fragment for inspection of the fracture level is necessary. If there is a deep fracture or longitudinal fracture making the tooth non-restorable, extraction of the tooth has to be performed.

Pulp treatment**Closed root apex**

Pulp extirpation and $\text{Ca}(\text{OH})_2$ application is preferred in the emergency phase in teeth with completed root development. Orthodontic or surgical extrusion may later be required to enable restoration of the tooth.

Open root apex

Regardless of the size of the exposure a superficial pulp amputation and temporary filling is performed (see crown fracture). To restore the tooth later, gingivectomy, ostectomy, orthodontic extrusion, or surgical extrusion can be performed.

Root fracture

The displaced coronal fragment may be repositioned (Fig. 39.17). A radiograph should be taken to check for correct repositioning. The tooth is splinted for 4 weeks. If the fracture is close to the cervical third then the tooth should be stabilized for longer (up to 4 months). Root canal treatment is not performed in the emergency phase of the treatment, because pulp healing is possible, even in cases with discoloration of the coronal fragment. Signs of pulp necrosis are watched for at follow-up visits. If pulp necrosis develops then root canal treatment of the coronal segment is performed, as the apical fragment normally contains vital pulp tissue.

Concussion

No treatment is needed. However, the injury should be documented in the records for follow-up purposes or later insurance claims.

Subluxation

Splinting is generally not necessary but a flexible splint to stabilize the tooth for patient comfort can be used for up to 2 weeks.

Lateral luxation

The tooth is repositioned manually with a finger in the vestibule or with forceps to disengage it from its bony lock and gently reposition it into its original location (Fig. 39.18). The tooth is stabilized for 4 weeks using a flexible splint. The pulpal condition is monitored in the weeks after trauma. If the pulp becomes necrotic, root canal treatment is indicated to prevent root resorption. In immature, developing teeth, revascularization can be confirmed radiographically by evidence of continued root formation and possibly by positive sensibility testing.

Extrusive luxation (extrusion)

Extruded teeth should be manually repositioned in the tooth socket and stabilized for 2 weeks using a flexible splint.

Intrusive luxation (intrusion)**Teeth with incomplete root formation**

Spontaneous re-eruption is allowed to take place. If no movement is noted within 3 weeks, rapid orthodontic repositioning is recommended.

Teeth with completed root formation

The tooth should ideally be repositioned orthodontically as soon as possible (Fig. 39.19). Surgical reposi-

Fig. 39.17 Treatment of root fracture by repositioning the coronal fragment and splinting. From Andreasen *et al.* 2007.²

Fig. 39.18 Treatment principle for lateral luxation: repositioning and splinting. From Andreasen *et al.* 2007.²

Fig. 39.19 (a) Intruded left central incisor. (b) Orthodontic repositioning. (c) Final result after 2 months.

tioning in the emergency phase is an alternative treatment but has been associated with periodontal attachment loss. The pulp will remain necrotic in intruded teeth with completed root formation, and root canal treatment using a temporary filling with Ca(OH)_2 is recommended within the first weeks.

Avulsion

See Fig. 39.20.

Advice immediately after the accident

An avulsed permanent tooth is a critical injury since the prognosis depends very much on what is done immediately after the injury. Instructions may have to be given by telephone to the patient or other people at the place of accident, e.g. parents, teachers, etc. The following instructions should be given:

1. Make sure it is a permanent tooth. (Primary teeth should not be replanted because of the risk of injury to the underlying permanent tooth.)
2. Keep the patient calm.
3. Find the tooth and pick it up by the crown (the white part) and avoid touching the root.
4. If the tooth is dirty, wash it briefly (10 seconds) under cool running water and reposition it. Try to encourage the patient/parent to replant the tooth. Hold it in position.
5. If this is not possible, place the tooth in a suitable storage medium, e.g. a glass of milk or in saline.

The tooth can also be transported in the mouth, keeping it between the molars and the inside of the cheek. Avoid storage in water.

6. Seek emergency dental treatment immediately.

At the clinic

A patient may come to the clinic with the tooth already replanted or with the tooth outside the mouth stored in a medium. Treatment must be related to the status of the root development (closed or open apex) because there is a chance for revascularization of the pulp in teeth with open apices.^{26–29} Another factor of importance is the status of the periodontal ligament cells. If the tooth has been immediately replanted or replanted within the first hour or stored in a suitable storage medium, such as milk, saliva, or a special storage medium there is a chance for healing.^{26–29} However if the tooth has been stored dry for more than 1 hour the periodontal ligament cells will be necrotic, healing with normal periodontal ligament cannot be expected, and the tooth will be subjected to later root resorption.^{11–14} Such teeth should still, in the majority of cases, be replanted in the emergency phase and final decisions on more definitive treatment should be taken at a later stage when all factors can be taken into consideration, such as tooth development, Angle class, congenitally missing teeth, growth status of the patient, etc. Such comprehensive planning will require a multidisciplinary approach together with other specialists, e.g. endodontists, orthodontists, prosthodontists, and pediatric dentists.

Fig. 39.20 Mechanism of avulsion. Frontal impacts lead to avulsion with subsequent damage to both the pulp and periodontal ligament (PDL). The vascular supply of the pulp is interrupted, the PDL attaching to the alveolar socket and the root surface is damaged. The extraoral time and environment determine the fate of the PDL and pulp after replantation. From Andreasen *et al.* 2007.²

In the emergency phase the following treatment should be carried out.

Avulsed permanent tooth with closed apex

The tooth has been replanted prior to the patient arriving at the dental office or clinic:

1. Do not extract the tooth.
2. Clean the area with water spray, saline, or chlorhexidine.
3. Suture gingival lacerations if present.
4. Verify normal position of the replanted tooth both clinically and radiographically.
5. Apply a flexible splint for up to 2 weeks.
6. Administer systemic antibiotics.
7. Evaluate the need for a tetanus booster.

8. Initiate root canal treatment 7–10 days after replantation and before splint removal by placing calcium hydroxide as an intracanal medicament until permanent filling of the root canal.

The tooth has been kept in special storage media, milk, saline, or saliva, and the extraoral dry time is less than 60 minutes:

1. If contaminated, clean the root surface and apical foramen with a stream of saline and place the tooth in saline. Remove the coagulum from the socket with a stream of saline before replantation.
2. Examine the alveolar socket. If there is a fracture of the socket wall, reposition it with a suitable instrument. Replant the tooth slowly with slight digital pressure. Suture gingival lacerations.
3. Verify normal position of the replanted tooth both clinically and radiographically.
4. Apply a flexible splint for up to 2 weeks.
5. Administer systemic antibiotics.
6. Evaluate the need for a tetanus booster.
7. Initiate root canal treatment 7–10 days after replantation and before splint removal by placing calcium hydroxide as an intracanal medicament until permanent filling of the root canal.

If the extraoral dry time is longer than 60 minutes, delayed replantation is carried out. The aim of delayed replantation is not to achieve normal periodontal healing. The expected final outcome is ankylosis and resorption of the root. However the retained root will prevent the alveolar process from atrophying. Fluoride has been reported to delay the rate of replacement resorption of the retained root.

The technique for delayed replantation is:

1. Remove attached necrotic soft tissue or the root with gauze. Root canal treatment can be done on the tooth prior to replantation through the open apex or during the first weeks after replantation.
2. Remove the coagulum from the socket with a stream of saline.
3. Examine the alveolar socket. If there is a fracture of the socket wall, reposition it with a suitable instrument.
4. Immerse the tooth in a 2% sodium fluoride solution for 20 minutes.
5. Replant the tooth slowly with slight digital pressure. Suture gingival lacerations.
6. Verify normal position of the replanted tooth clinically and radiographically.
7. Splint the tooth for 4 weeks.
8. Administer systemic antibiotics.
9. Evaluate the need for a tetanus booster.

During follow-up, ankylosis and replacement resorption are expected in the first year. If there is infraposition of the tooth crown of more than 1 mm, it is recommended to perform decoronation to preserve

the contour of the alveolar ridge. This procedure should be reserved for patients with remaining vertical growth.^{30–33}

Avulsed permanent tooth with open apex

The tooth has already been replanted prior to the patient arriving in the dental office or clinic:

1. Clean the area with water spray, saline, or chlorhexidine.
2. Do not extract the tooth. Suture gingival lacerations if present.
3. Verify normal position of the replanted tooth both clinically and radiographically.
4. Apply a flexible splint for up to 2 weeks.
5. Administer systemic antibiotics.
6. Evaluate the need for a tetanus booster.
7. If revascularization of the tooth pulp does not occur within the first months, root canal treatment may be recommended.

The tooth has been kept in special storage media, milk, saline, or saliva, and the extraoral dry time is less than 60 minutes:

1. If contaminated, clean the root surface and apical foramen with a stream of saline. Topical antibiotics can be considered.
2. Remove the coagulum from the socket with a stream of saline and then replant the tooth.
3. If there is a fracture of the socket wall, reposition it with a suitable instrument. Replant the tooth slowly with slight digital pressure.
4. Suture gingival lacerations, especially in the cervical area.
5. Verify normal position of the replanted tooth clinically and radiographically.
6. Apply a flexible splint for up to 2 weeks.
7. Administer systemic antibiotics.
8. Evaluate the need for a tetanus booster.
9. If revascularization of the tooth pulp does not occur within the first months, root canal treatment may be recommended.

If the extraoral dry time is longer than 60 minutes, delayed replantation is carried out. The aim of delayed replantation is not to achieve normal periodontal healing. The final outcome is ankylosis and resorption of the root. However the retained root will prevent the alveolar process from undergoing severe atrophy. Fluoride has been reported to delay the rate of replacement resorption of the retained root.

The technique for delayed replantation is:

1. Remove attached necrotic soft tissue with gauze. Root canal treatment can be done on the tooth prior to replantation through the open apex or the first weeks after replantation.
2. Remove the coagulum from the socket with a stream of saline.

3. Examine the alveolar socket. If there is a fracture of the socket wall, reposition it with a suitable instrument.
4. Immerse the tooth in a 2% sodium fluoride solution for 20 minutes.
5. Replant the tooth slowly with slight digital pressure. Suture gingival lacerations.
6. Verify normal position of the replanted tooth clinically and radiographically.
7. Splint the tooth for 4 weeks.
8. Administer systemic antibiotics.
9. Evaluate the need for a tetanus booster.

During follow-up, ankylosis and replacement resorption are expected in the first year. If there is infraposition of the tooth crown of more than 1 mm and the patient is still in a growth active period, it is recommended to perform a decoronation procedure to preserve the contour of the alveolar ridge.^{30–33}

Splinting of TDI

After emergency treatment of TDI where teeth and root fragments have been repositioned, there is a need for splinting to stabilize the injured tooth in the initial healing period. However splinting may also have adverse effects on healing, such as increased risk for ankylosis and osseous replacement resorption or compromised revascularization of the pulp if splinting is not done well. Bars used for maxillomandibular fixation in jaw fracture treatment are not suitable for splinting of luxated or replanted teeth

Fig. 39.21 Titanium trauma splint. (Courtesy of Dr von Arx, Berne, Switzerland.)

because there is a risk for extrusion of teeth due to the fact that the preformed bar does not have any occlusal curve built in. Hence, the bar will extrude the luxated teeth.

Since the discovery of adhesive techniques, dental splints have been made by an acid-etched bonding technique which fulfills most requirements of a modern splint. An optimal splint should enable some micromovements of the injured tooth, allowing it to move a little bit during the healing phase. This can be achieved either by the splint being flexible, by combining the bonding material with a wire to allow for flexibility, or by not stretching out the splint too far.

The bonding material can be combined with a steel wire, twist flex wire, nylon fishing line, fiberglass or titanium splint. Some examples of splints can be seen in Figs 39.21–39.23. The splinting period should ideally be related to the type of TDI. The periods shown in Table 39.1 have been recommended by an expert group of IADT.^{18,19,34}

TDI in the primary dentition

Similar diagnosis and classification principles are applied to primary teeth. However the treatment of primary teeth is often modified and consideration must always be given to the underlying permanent tooth germs. For this reason primary teeth must never be replanted. Moreover, a primary tooth that has been dislocated in the direction of the permanent underlying tooth germ should be extracted, while dislocation away from the underlying tooth germ may allow the primary tooth to be repositioned and

Table 39.1 Splinting periods for various TDI requiring fixation.

TDI	Splinting period
Subluxation	(2 weeks)
Extrusive luxation	2 weeks
Avulsion	2 weeks
Lateral luxation	4 weeks
Root fracture (middle third)	4 weeks
Root fracture (cervical third)	4 months

Fig. 39.22 Patient with mandibular body fracture and luxated incisors. (a) The mandibular fracture has been splinted by plate and screw osteosynthesis. (b) A separate fiberglass splint has been applied to the luxated and repositioned teeth. The use of separate splints will enable optimized splinting time and type.

Fig. 39.23 Splinting using fiberglass and resin. (a) A string of fiberglass. (b) The fiberglass is bonded to the acid-etched enamel of the luxated tooth and the adjacent teeth. (c) Finished splint.

kept. A primary tooth should not be kept if it poses a risk for the permanent tooth because of infection. Other modifying factors when treating traumatized primary teeth are maturity of the child, caries, tooth development, occlusion, and time for exfoliation. For more detailed information regarding treatment of primary teeth after trauma see textbooks and manuals^{2,16} or recent guidelines for primary teeth.³⁵

Complications

Pulpal complications

The pulpal complications that commonly occur after dental trauma can be categorized as pulp canal obliteration (PCO), pulp necrosis, and internal root resorption. The incidence of such complications varies among traumatized teeth, depending on the type of the trauma and how it was managed.

Pulp canal obliteration

Partial or complete obliteration of the pulp canal is characterized by deposition of hard tissue within the root canal space and yellow discoloration of the clinical crown. This can be recognized clinically as early as 3 months after the injury. PCO is seen commonly after luxation injuries and horizontal root fractures in young adults. On clinical examination the tooth appears darker in hue than the adjacent teeth and exhibits a dark yellow color due to decrease in trans-

lucency from a greater thickness of dentin under the enamel.

Approximately 3.8–24% of traumatized teeth develop varying degrees of PCO. Studies indicate that the yearly incidence of pulpal necrosis occurring in these teeth is <1%. A tooth with PCO does not need root canal treatment unless there is evidence of periradicular radiolucency or the tooth becomes symptomatic. If the pulp tissue becomes necrotic and a periradicular radiolucency develops, non-surgical root canal treatment has been shown to be successful in 80% of cases.

Pulp necrosis

This is a common sequel of traumatic injuries; the incidence increases with the severity of the injury and in cases where the roots are fully formed. Pulp necrosis also depends on the type of injury. If pulp necrosis is detected then root canal treatment should be initiated immediately to prevent inflammatory root resorption.

Internal root resorption

This process of root resorption is usually detected radiographically. The radiographic appearance is typically a radiolucent lesion occurring in the middle of the root with loss of the outline of the pulp canal space. The presence of vital pulp tissue is a prerequisite for this to occur and usually it is asymptomatic. If detected early then root canal therapy should be initi-

ated and the prognosis can be excellent. If the resorptive defect is large, rendering the tooth compromised, then the risk of root fracture is increased. Follow-up radiographs are an essential means of detection and management.

Periodontal complications

When luxation injuries occur, the periodontal membrane is torn and damaged against the bone walls. This membrane can also be injured as its cells become exposed to drying or to a non-physiological environment. Provided infection does not intervene, healing of small injured areas may take place spontaneously. Two complications that may occur are inflammatory root resorption and dentoalveolar ankylosis.

Infection-related (inflammatory root) resorption

If the pulp is infected in a tooth that has been exposed to injuries to the root cementum and periodontal membrane then serious complications may occur. Inflammation on the root surface may be maintained by the necrotic infected pulp through osteoclastic exposure of dentinal tubules. If the necrotic pulp is not removed the tooth will be quickly resorbed. Infection-related resorption can be detected on radiographs as radiolucent root resorption cavities. Infection-related root resorption can be treated by debridement of the canal space and application of $\text{Ca}(\text{OH})_2$ dressing. Because some dental injuries have an extremely high risk of Infection-related root resorption, the pulp should always be extirpated

Fig. 39.24 Radiograph of an ankylosed incisor. Root resorption with osseous replacement is seen.

when treating such dental injuries; in other injuries revascularization of the pulp and healing may occur.

Dentoalveolar ankylosis

If large areas of the periodontal membrane have been injured, either by trauma itself or as a result of Infection-related root resorption, the remaining periodontal membrane cells cannot produce a new periodontal membrane. Instead, bone will grow into these defective areas and the tooth will be united with the alveolar bone, resulting in dentoalveolar ankylosis. This is a serious condition for the tooth in that the tooth will be replaced by bone and will be eventually lost. Radiographically bone is seen replacing the tooth substance (Fig. 39.24). This process is called replacement resorption or osseous replacement. In adults this replacement resorption will proceed slowly and the tooth may stay in place for several years. However in young individuals, where growth is not yet completed, the replacement is much faster and furthermore, dentoalveolar ankylosis will interfere with the growth of the alveolar process and the tooth will be infrapositioned (Fig. 39.25). It is therefore important to diagnose dentoalveolar ankylosis early. A high metallic percussion sound can be heard when a percussion test of the tooth is per-

Fig. 39.25 Infraposition of left central incisor as a result of ankylosis after trauma. The tooth had a high percussion sound.

Fig. 39.26 Decoronation of ankylosed incisor. The root is left in the bone for osseous replacement, keeping the width of the alveolar process.

formed. If ankylosis is diagnosed in a growing patient decoronation may be necessary and a multidisciplinary approach is recommended for treatment planning and coordination with the patient's growth status and dental development.^{30–33}

Summary

Oral and maxillofacial surgeons will regularly see many trauma patients. TDI occur frequently and are often seen simultaneously with other oral and maxillofacial injuries. The prognosis for some TDI is highly dependent on prompt and correct emergency management. Hence the oral and maxillofacial surgeon should have knowledge to manage dental injuries in the emergency phase. This chapter has presented the basic knowledge needed for such management.

Chapter 40

Midfacial Fractures

Petr Schütz and Lars Andersson

The maxillofacial region is important, with vital functions such as breathing, eating, talking, smelling, and vision. Moreover, it is also an esthetically important region. Injuries to the maxillofacial region may, therefore, have serious consequences for the individual's quality of life.

Earlier used methods, of conservative treatment of maxillofacial fractures with suspension wires and intermaxillary fixation, have been replaced by methods aiming at exposing fracture lines, allowing precise alignment and application of osteosynthesis hardware and enabling a faster return to function. The aim of this chapter is to give an overview of modern treatment principles in the management of fractures of the midface by describing surgical approaches, techniques, and strategies for fracture treatment. A section on biodegradable osteosynthesis material is also presented.

Midfacial skeleton as a three-dimensional structure

The midface skeleton (Fig. 40.1) is a complex structure composed of multiple, mostly paired, bones intimately linked by sutures. It is connected to and supported by bones of the neurocranium, namely frontal bone, sphenoid bone, and temporal bone. In individuals with preserved dentition, further support is provided by mandible via contact of the dental arches.

The midface can be viewed as a labyrinth of air-containing cavities, with the exception of the orbits, surrounded by thin bony lamellae with rims of thick bone (Fig. 40.2). These thicker rims constitute a system of pillars and struts resembling the framework of a building, and the position and stability of each is interrelated.¹ The midface buttress system comprises

Fig. 40.1 Midfacial area highlighted.

Fig. 40.2 The midface as a system of cavities: O, orbits; E, ethmoidal sinuses; M, maxillary sinuses; N, nasal cavities.

Fig. 40.3 Projection of masticatory forces through the vertical pillars of the midface.

vertical, horizontal, and sagittal components, of which the sagittal component is the weakest.²

The well defined, paired **vertical buttresses** (Fig. 40.3) are: (1) nasomaxillary (made up of the frontal process of the maxilla); (2) zygomatico-maxillary (made up of the zygomatico-alveolar crest, body and frontal process of the zygoma); and (3) pterygomaxillary (made up of the pterygomaxillary junction and the pterygoid process of the sphenoid bone). These buttresses developed as an adaptation to masticatory forces that are transmitted by them to the skull base. The **horizontal buttresses** include the superior and inferior orbital rims, maxillary alveolus and palate, serrated edges of the greater wings of the sphenoid bone and the zygomatic arches.³ The **sagittal buttresses** are represented by zygomatic arches, while the central part of the midface lacks a strong sagittal buttress (Fig. 40.3).²

The main objective of fracture repair of the midface is the reconstruction of these buttresses using osteosynthetic devices. These buttresses are robust enough bony structures to allow secure insertion of screws. The exceptions are the pterygomaxillary buttresses and the sphenoid greater wings, which are not surgically accessible.

The ratio between the small bone volume of the midface and its large surface area provides an excellent blood supply despite the absence of large nutritive vessels. Consequently, fractures of the midface heal and remodel fast and well and are resistant to infection. On the other hand this unique healing capacity can also complicate management of fractures if there is a delay in treatment.

Classification

There are several systems for classification of midface fractures. Fractures can comprise single or multiple fracture lines in the same bone or have fracture lines that communicate with each other, so-called comminuted fractures. Fractures can also be of the greenstick type which is often seen in young children where the bone is not so highly mineralized.

Fractures can also be classified as closed, when there is no communication with the outer environment through lacerations in the skin, oral mucosa, and gingiva, or through a gingival pocket. An open fracture is defined as a fracture where there is such a communication through a laceration or when the fracture is engaging a dentate area. A fracture can also be complicated if there is a considerable injury or defect in the overlying soft tissue.

Fractures can also be classified in relation to the first or secondary place of energy release. A direct fracture occurs where the first impact takes place, e.g. a blow to the cheek resulting in a zygomatico-maxillary fracture, while an indirect fracture happens in the region of the zygomatic arch and possibly also the skull base.

Orbital fractures are often classified as blow in or blow out, depending on the way the orbital walls are fractured. When most of the maxillofacial bones are engaged in a trauma the term panfacial fracture is used. From a clinical and treatment point of view, classification using the above terminology in combination with a classification related to the anatomic site of the midface fracture is most often used.

René Le Fort's (French surgeon, 1869–1951) experimentally based categorization of midfacial fracture patterns is the most popular one.⁴ This simple classification system distinguishes three fracture patterns (Fig. 40.4):

- Le Fort I (also known as Guérin fracture,⁵ after Alphonse Guérin, French surgeon, 1816–1895), separates the whole complex of alveolar and palatal processes of the maxilla, horizontal plates of the

Fig. 40.4 Le Fort fracture patterns.

palatal bones and lower parts of the pterygoid plates just above the pterygo-maxillary junction;

- Le Fort II (also known as "pyramidal" fracture) separates the whole maxilla with part of the nasal bones and the lower part of the pterygoid plates;
- Le Fort III separates both zygomatico-maxillary complexes plus the nasal bones, palatal bones and most of the pterygoid plates, from the rest of the cranium.

However, in clinical practice Le Fort types of fractures are very rarely encountered in pure forms as described above. In most instances the fracture lines of particular types combine in quite unpredictable, often

asymmetric patterns (Fig. 40.5). The reason for this variability rests with the many different trauma mechanisms and high energies involved, which were not predicted and were perhaps unimaginable in the time when René Le Fort performed his experiments.

There are other, very common and historically recognized fracture patterns that do not fit into the Le Fort classification. Prominent among them is a fracture of the zygomatic bone, first reported by Joseph Duverney (French anatomist, 1648–1730).⁶ This is currently described as zygomatico-maxillary complex (ZMC) fracture,⁷ or zygomatico-orbital fracture,⁸ because the zygomatic bone is almost never involved alone, as it is in intimate contact with the temporal, frontal, sphenoid, and maxillary bones (Fig. 40.6). An isolated fracture of the zygomatic arch is a separate clinical entity.

Nasal bone fractures are given little attention in maxillofacial literature, perhaps because they are mostly isolated and managed by ear, nose, and throat (ENT) surgeons. Despite that, they are the most frequent facial fractures in general.^{9–12}

Another clinically useful concept is the one of naso-orbito-ethmoid (NOE) fracture.¹³ It reflects the

Fig. 40.5 3D CT of panfacial fracture with patterns of all three Le Fort fractures recognizable.

Fig. 40.6 Schematic drawing of zygomatico-maxillary complex fracture.

fact that high-energy injuries to the nasal area break and displace bony structures involving the nasal bones, and also the frontal processes of the maxilla, the lacrimal bones and the ethmoid bone (Fig. 40.7). A very similar term is frontonasal fracture, which describes the concomitant involvement of the nasal part of the frontal bone, and especially of the fronto-nasal ostium.¹⁴

The diagnosis of the sagittal palatal fracture is important (Fig. 40.8), although it always occurs in combination with other fractures, often of Le Fort type.¹⁵

The term orbital fracture¹⁶ can mean any fracture involving either the orbital rim or the orbital wall. In clinical practice it is usually understood to be a fracture of the orbital walls.

It is obvious that above-mentioned terms and definitions are useful in the description of topographically limited injuries, but when it comes to complex midfacial fractures, a list of separate diagnoses is usually developed. These diagnoses often overlap when adjacent areas of the midface are affected. Moreover, complex fracture patterns can be described in more than one way. This makes communication between clinicians difficult and can have insurance, billing and medico-legal repercussions. On the other hand to describe each fracture line separately would be too intricate, laborious, and perplexing. To overcome this

Fig. 40.7 Schematic drawing of naso-orbito-ethmoidal fracture.

Fig. 40.8 Schematic drawing of parasagittal fracture of the hard palate.

problem, there have been many attempts to develop comprehensive descriptive and scoring systems which are mentioned here briefly for completeness.^{17–21} The system of Cooter and David¹⁷ is alpha-numerical coding of skull fractures, coding fracture sites alphabetically and their severity numerically. A similar elaborate system, more suitable for research than for clinical use, providing detailed analysis of fracture pattern and severity, was developed by Buitrago-Téllez *et al.*¹⁸ The system devised by Guerrissi¹⁹ aims at quantification of severity of maxillofacial injuries for the purpose of evaluation of esthetic and functional impact as well as identification of patients with potentially life-threatening injuries. This system unfortunately brings together bone and soft tissue injuries, which makes interpretation difficult. Donat *et al.*²⁰ base their classification on the effect on skeletal supportive beams and buttresses. Follmar *et al.*²¹ offer a hierarchical system integrating classical anatomic nomenclature and established fracture patterns, avoiding descriptive duplicity.

From a clinical point of view it is practical to use the classification system in Table 40.1.

Epidemiology

The peak incidence of maxillofacial fractures is in the age range of 20–30 years.^{22–30} The incidence is higher in males.^{22–31} The etiological factors vary with societies and geographic location in the world.^{22–51} In developing countries road traffic accident is the main cause of maxillofacial injuries; in more developed countries there has been a decrease in the proportion of road traffic accidents as etiologic factors, especially in the past three decades, due to a more developed and safer traffic environment and the use of seat belts.^{23–25,27–31,37} Many studies have reported that a life style with high alcohol consumption is a major contributing factor.^{22–25,27,30,40,44,47,48,53–60} In contrast there are other societies in the world where alcohol consumption does not play a major role in the etiology of facial fractures because it is forbidden due to religious and cultural reasons.^{25,26,29,34,35,39,41}

Maxillofacial injuries due to sports are frequently seen; the etiology varies as different sports are played in different geographic locations.^{23,61–70} The use of helmets and mouth guards can prevent some injuries. In developing countries, fall injuries are more common due to lack of safety measures.^{23,26,28,49,56}

Throughout history there have been maxillofacial injuries caused by weapons. The head and neck region is affected in 16% of all war injuries.⁷¹ Weapons have developed from low velocity to high velocity, and in recent years blast injuries from landmines and roadside bombs have become more common.⁷² In some societies, where there is easy access to weapons, gunshot injuries occur frequently during peace time, and maxillofacial injuries are sustained due to gunshot injuries caused by crimes and suicide attempts.⁷³

Assessment of patients with midface injuries

Assessment of the injured maxillofacial patient is presented in detail in Chapter 38. It is important to take a thorough history. Since many patients are unconscious there are often only reports from eyewitnesses. Such reports are not always reliable.

Patients with midface fractures are often examined and treated with a multidisciplinary approach. Responsibilities and routines vary with traditions worldwide. In recent decades the oral and maxillofacial surgeon has taken an increasing responsibility for midface injuries and today is often the leader of the team. Ophthalmologists are consulted for eyeball trauma, blindness, and problems regarding vision, ENT specialists have to be consulted for vertigo and hearing problems related to trauma, and neurosurgeons must be consulted when there is cerebrospinal fluid leakage and when intracranial bleeding or air is suspected. Plastic surgeons are consulted when there are large soft tissue defects.

Open or closed reduction

In contrast to the mandible where some fractures can still be treated non-surgically with intermaxillary fixation in a cooperative patient, the majority of midface fractures are treated surgically. In the past, suspension wiring techniques, aimed at stabilizing the fractured bone to a more superiorly located stable non-fractured bone, were used. However, it was difficult to achieve and maintain proper reduction with these techniques.

In recent decades bone plates and screws have been developed. These are mostly made of titanium. The principle is to expose, reduce, and stabilize the fractures by rigid fixation using the plates and screws. Treatment should ideally be carried out in the emergency phase within the first 24 hours, and if these conditions cannot be met, treatment should be

planned within the first week. Longer delay may result in difficulties in repositioning the fragments.

Surgical approaches to midfacial skeleton

The aim of surgical approaches to midfacial fractures is to enable wide subperiosteal exposure of all fracture lines, precise alignment, and application of osteosynthesis hardware. This should be achieved with minimal additional morbidity and minimal permanent consequences.⁷⁴ Special considerations are given to cosmetic effect of resulting scars, preservation of function of branches of facial and trigeminal nerves, and avoidance of major vessels during surgery. These goals are best met by an intraoral approach.

While the whole mandible can, in principle, be approached surgically from intraoral incisions, sometimes with assistance of an endoscopic technique when operating on condyles, the intraoral approach offers exposure of midfacial skeleton limited to the anterior and inferior parts of the maxilla and palate. Everything above the level of the infraorbital rims must be accessed through the skin or trans-conjunctival incisions.

Intraoral incisions

Intraoral incisions in management of midfacial fractures are usually limited to the upper vestibule and alveolar process. The palatal mucosa must be incised only very rarely, to enable plating of a sagittal palatal fracture or to facilitate the suture of an associated laceration.

Disinfection of the mucosal surface before incision is not necessary. However in some trauma patients, oral hygiene is compromised and the mouth should be copiously irrigated with saline and mechanically cleaned with moist gauze if necessary. Infiltration of the submucosa with local anaesthetic with vasoconstrictor will reduce the initial bleeding and make dissection fast and comfortable.

The upper vestibular incision starts at the level of the first molar about 1 cm above the attached gingiva and proceeds anteriorly, sloping slightly caudally, so that it leaves a cuff of about 5 mm of loose mucosa at the upper labial frenum. An incision placed too high posteriorly will violate the attachment of the buccinator muscle and cause the buccal fat to enter into the operation field. The incision is usually accomplished in two steps, firstly cutting mucosa and then periosteum at the base of the alveolar process. Dissection then proceeds subperiosteally. It can reach the inferior orbital margin and the body of the zygomatic bone. The periosteum can be undermined over the maxillary tuber up to the pterygomaxillary suture. The infraorbital neurovascular bundle should always be identified and protected (Fig. 40.9). The margin of the

piriform aperture should be identified medially and the nasal mucosa protected.

In the presence of gingival and mucosal lacerations, these should be incorporated into the incision if feasible. This means that sometimes a marginal mucoperiosteal flap will be created to avoid ischemia of lacerated superiorly pedicled flaps.

Closure of a buccal sulcus incision is usually accomplished in one layer with either continuous or interrupted mattress sutures. Sufficiently deep bites of tissue should be taken to prevent dehiscence. In the case of bilateral incision (horseshoe-shaped incision), consideration should be given to using the nasal alar base cinch suture and V-Y plasty of upper lip mucosa to prevent widening of the nose and shortening of the upper lip.

Displaced fractures of the hard palate are sometimes accompanied by laceration of the mucoperiosteum (Figs 40.10 and 40.11). Some undermining of margins and extension may be required to enable application of a fixation device. Suturing can be, however, difficult, especially if mucosal margins are crushed or defective. In such a situation, parallel releasing incisions and undermining, creating bipediced flaps, can help, as in cleft palate surgery.

Fig. 40.9 Fractured zygomatico-maxillary complex exposed from upper vestibular incision. White arrow indicates the infra-orbital nerve.

Fig. 40.10 Parasagittal displaced fracture of the maxilla with laceration of hard palate mucosa.

Midfacial degloving by intraoral incision

Midfacial degloving is an extension of a horseshoe-shaped intraoral incision achieved by releasing the skeletal attachment of the nose and retraction of its soft tissue envelope cranially, so that the inferior and medial orbital margins and nasal bones are exposed. This approach is seldom used in management of acute trauma, but can be advantageously used in secondary reconstruction of the naso-orbito-ethmoidal (NOE) and frontonasal area.⁷⁵ In these cases it can replace the much more time-consuming coronal incision.

Periorbital incisions

The sheer number of periorbital incisions in use shows that none of them is applicable in all clinical situations. Some of them are fraught with a high percentage of cosmetically unfavorable outcomes and are currently criticized or even have already been abandoned. Among widely discarded approaches are prominent infraorbital and lateral eyebrow incisions. The subciliary incision may possibly also be abandoned in the future. The discussion in the literature currently concentrates on the following controversies: sub tarsal incision⁷⁶ versus transconjunctival incision⁷⁷ and transconjunctival incision with⁷⁸ or without⁷⁹ lateral canthotomy. To give the reader a full understanding of the topic, all incisions will be described, even those the authors do not use any more. Detailed anatomy of this extremely complex region is to be found elsewhere.⁸⁰

Infraorbital incision

The infraorbital incision is located over or slightly below the inferior orbital margin, preferably in a skin crease. The incision should be sloped caudally in medio-lateral direction and horizontal extension should be avoided to prevent violation of lymphatic

Fig. 40.11 Laceration sutured after reduction of fracture with help of para-alveolar releasing incision and undermining of resultant bipediced flap.

drainage resulting in long-lasting lymphatic edema. After incising skin, blunt dissection proceeds directly through fibers of the orbicularis oculi muscle to the orbital margin above the infraorbital foramen and the attachment of the mimic muscles. The periosteum is incised 2 mm below the orbital margin and dissected with a sharp periosteal elevator. If orbital floor is to be explored, dissection continues behind the orbital margin in close contact with bone, avoiding perforation of periosteum (Figs 40.12 and 40.13).

Closure is done in two layers: the periosteum is reattached by 4/0 resorbable suture and the skin by running intradermal 5/0 monofilament suture.

The advantages of this approach are technical ease, wide exposure, and no risk of ectropium or scleral show. The disadvantage is a prominent scar.

Subtarsal incision

The subtarsal incision is located just under the inferior margin of the lower tarsal plate that is at least 5 mm below the lid margin, usually in the first skin crease. The incision is either directly deepened through the orbicularis muscle, or stepped caudally. Dissection proceeds above the orbital septum and parallel with

Fig. 40.12 Subtarsal and infraorbital incisions and dissecting paths.

Fig. 40.13 Fracture of the inferior orbital rim exposed through infraorbital incision.

it caudally, towards the inferior orbital margin. The rest of the procedure is identical to infraorbital incision (Fig. 40.14).

This incision provides very good cosmetic results and has a low risk of ectropium or scleral show. Currently it seems to be the preferred cutaneous lower lid incision (Figs 40.15 and 40.16).

Fig. 40.14 Subtarsal incision: incision in skin crease of lower lid.

Fig. 40.15 Subtarsal incision: exposure of fracture of inferior orbital rim.

Fig. 40.16 Subtarsal incision: appearance of scar camouflaged in skin crease 6 months after operation.

Subciliary incision

The incision is done 2mm below the eyelashes and commences at the level of the inferior lacrimal punctum. It proceeds laterally along the whole width of the eyelid and can be extended up to the lateral orbital margin in a skin crease. After incising the skin, it is possible to cut directly through the orbicularis oculi muscle and proceed with dissection in the same manner as in the subtarsal incision. Another option is to dissect about 2mm caudally between the skin and the muscle and divide the muscle after that in a stepwise manner. The third option, now largely discarded, is to dissect subcutaneously to the orbital margin and cut muscle only there (Figs 40.17 and 40.18). This method of dissection is most prone to complications. The rest of the dissection is again identical to the previous approaches.

Subciliary incision results in a nearly imperceptible scar, however it is technically much more difficult and, unfortunately, it is fraught with a high incidence of complications. Up to 40% of patients develop scleral show or even ectropium.⁷⁸

Transconjunctival incision

The lower eyelid is retracted by a Desmarres lid retractor or 5/0 silk stay sutures through the tarsal

Fig. 40.17 Schematic drawing of three different variants of subciliary incision.

Fig. 40.18 Fracture of the inferior orbital rim exposed through subciliary incision.

plate. Some authors recommend use of a corneal shield to prevent corneal abrasions, but in our opinion it is not necessary. The cornea is usually satisfactorily protected by the upper eyelid, or can be covered by a conjunctival flap suspended by a suture. It is important to check the size of the pupil frequently if dissection reaches deep into the orbit close to the optic foramen and nerve. Use of a corneal shield makes this uncomfortable, so a corneal shield may not be used. The conjunctival incision is made between the lower margin of the tarsal plate and the conjunctival fornix. It is then deepened through the lower lid retractor and capsulo-palpebral fascia. The orbital margin is reached by spreading the prolapsing orbital fat with fine dissecting scissors. The periosteum is incised just behind the inferior orbital margin so that the orbital septum remains intact.

Closure consists of just suturing the periosteum; suturing the conjunctiva is not necessary. It is a good idea to mark the periosteal margins by a suture at the beginning of the orbital dissection to identify them easily during closure. The above-described procedure is known as retroseptal transconjunctival approach and is also widely used in cosmetic eyelid surgery.⁸¹

Alternatively a preseptal approach has been described, which avoids the orbital fat, but is technically more demanding and has a higher complication rate than the retroseptal procedure.⁸² The incision is made just under the inferior margin of the tarsal plate and dissection proceeds between the orbital septum and the preseptal part of the orbicularis muscle to the orbital rim, where the periosteum is incised below the orbital septum attachment (Fig. 40.19).

The transconjunctival incision without lateral canthotomy provides somewhat limited access, especially in young individuals with tight lids (Fig. 40.20). On the other hand it is cosmetically perfect since it leaves no visible scar.

Lateral canthotomy

The lateral canthotomy commences with about a 5mm long skin incision running horizontally from

Fig. 40.19 Schematic drawing of transconjunctival incision with preseptal and retroseptal dissection paths.

Fig. 40.20 Exposure of the orbital floor through transconjunctival retroseptal approach.

the lateral eyelid commissure. The incision should not extend beyond the lateral orbital margin. The skin is undermined with fine scissors caudally and the lower limb of the lateral palpebral ligament is identified as a tough whitish strip. The lower lateral margin of the eyelid is pulled medially using Adson forceps and the stretched lower limb of the ligament is divided with scissors. This enables free retraction of the lower eyelid and dissection can continue with a transconjunctival incision as described above. Combination of a lateral canthotomy and a retroseptal conjunctival incision makes orbital floor dissection easy and clear. It provides a kind of bird's eye view of the orbital floor and the infero-medial wall (Fig. 40.21).

With extension of the skin incision to about 1 cm and division of both limbs of the lateral palpebral

ligament, the periosteum can be stripped from the lateral orbital margin up to above the zygomatico-frontal suture. This will enable reduction and fixation of fractures in this area from the same approach as fractures of the lower orbital rim and floor (Fig. 40.22).⁸³

In closure of this approach, meticulous reattachment of the lateral canthus is of utmost importance. Failure to reconstruct the lateral palpebral ligament properly will result in rounding of the lateral palpebral angle and shortening of the palpebral fissure. The upper lateral margin of the inferior tarsal plate must be engaged by non-resorbable 5/0 monofilament suture and fastened tightly to the periosteum on the inner side of the lateral orbital margin at the

Fig. 40.22 Lateral canthotomy used for simultaneous approach to inferior and lateral orbital rim. (a) Inferior orbital rim plated and orbital floor reconstructed with titanium mesh. level of Whitnall's tubercle. If the periosteum here was stripped or damaged by the dissection, the suture can be fixed to a drill hole, screw or miniplate. It is always better to overcorrect the suspension of the ligament in a cranial direction than to undercorrect it, because some loosening of suspension usually occurs in the postoperative period. If also the upper limb of the ligament was cut, it must be resuspended as well. The skin is closed with 6/0 monofilament sutures, with particular care to close the lid commissure precisely.

A disadvantage of lateral canthotomy is an external scar, which, however, is short and usually well camouflaged in periorbital wrinkles (Fig. 40.23). Imprecise resuspension of the lateral palpebral ligament can also result in a cosmetic problem.

Lateral eyebrow incision

This is an easy way to expose the fronto-zygomatic suture and apply osteosynthesis hardware. The incision, about 2 cm long, is made in the lateral eyebrow and can be directly deepened down to periosteum. The incision line should be kept straight without curving it alongside the supero-lateral orbital margin. Shaving of eyebrow hair is not necessary; actually it should be avoided because regrowth of the eyebrow is often irregular. If needed, the incision can be elongated medially and stop short of the supraorbital foramen. Unfortunately the eyebrow thins laterally in many individuals and the scar can be quite prominent in such circumstances.

Upper blepharoplasty incision

This approach takes advantage of the extreme laxity of the skin and subcutaneous tissue of the upper eyelid. The incision is made in a skin crease of the upper eyelid, just penetrating the orbicularis muscle and avoiding damage to the deeper attachment of the levator aponeurosis and the orbital septum. A musculocutaneous flap is then undermined and pulled cranio-laterally so that the periosteum of the orbital margin comes into view. This is then incised and

Fig. 40.23 Appearance of lateral canthotomy scar 1 month after operation.

retracted to expose the zygomatico-frontal area of the orbital margin. Closure is done in two layers: the periosteum is closed with 4/0 Vicryl, and the skin is sutured with 6/0 monofilament. The incision regularly gives excellent esthetic results (Fig. 40.24).

Coronal incision

In principle, the coronal incision follows, and extends below, the course of the coronal suture of the neurocranium, which is the suture between the frontal bone and the parietal bones. The incision always reaches across the temporal area to the superior attachment of the external ear and often continues caudally as far as the attachment of an earlobe. Sometimes the term bicoronal incision is used to denote the full extent of it, as opposed to a hemicoronal incision that is employed unilaterally.

A fully developed coronal flap provides access to the frontal bone, zygomatic arches, bodies of the zygomatic bones, medial, superior and lateral orbital margins and much of the corresponding orbital walls, as well as the nasal bones. By preauricular extension it is possible to address the temporomandibular joint and the upper neck of the condylar process of the mandible. It also allows harvesting of calvarial bone grafts.

Most authors state that there is no need to shave the hair, or that a 2 cm strip of shaven skin is suffi-

cient.⁸⁴ In the authors' opinion, this is valid for female patients with long hair, which can be divided by a comb and braided. Females are also understandably more distressed by the prospect of hair shaving than males. In consenting male patients, the authors see no harm in a complete hair shave, which makes suturing of the flap much more comfortable and subsequent wound care easier and more hygienic (Fig. 40.25).

Fig. 40.24 (a) Upper blepharoplasty incision approach to zygomatico-frontal component of ZMC fracture. (b) Favorable appearance of scar 1 month after operation.

Fig. 40.25 Skin preparation for coronal incision. (a) Combing and braiding of hair in a female patient. (b) Shaving of 2 cm strip of skin in a female patient. (c) Full head shave in a male patient; zig-zag pattern incision line is marked with surgical pen.

After proper skin disinfection and draping the planned line of incision is marked with a surgical pen. The incision line runs from ear to ear across the top of the head either straight or in a zig-zag or sinuous fashion.⁸⁵ There is always some hair loss in the incision line and the scar is much less prominent if it is not straight, especially in a patient with a short hair-cut. The placement of the incision line should take into consideration future balding patterns in men, and anterior migration of the scar due to growth of the neurocranium in young children.⁸⁶ There is no advantage in placing the incision more ventrally, because the extent of exposure is given by the caudal extent of the incision: the lowest points define the axis around which the flap will rotate.

The three superficial layers of the scalp make up one functional unit.⁸⁷ Vascularization is very rich and, due to the presence of fibrous septa, the vessels gape and bleed profusely when cut. After marking the incision the sub-galeal layer is infiltrated with saline or diluted local anesthetic with vasoconstrictor (e.g. adrenalin 1:200 000). This reduces the initial bleeding and makes establishment of the proper dissection level easier. The incision starts on the top of the head and progresses step by step latero-caudally to both sides, while arresting bleeding after each step (Fig. 40.26). The incision penetrates through the skin, subcutaneous tissue, and galea aponeurotica, and stops just above the pericranium. The fourth layer of loose areolar tissue is the level of flap development. Dissection inside this level is initially facilitated by undermining the incision line with a spreading hemostat. Hemostasis is mainly achieved by compression of wound margins by Raney clips, Tessier scalp clamps or a running interlocking silk suture. A use of electrocautery should be minimized and only bipolar coagulation should be employed to protect hair follicles.

After the whole length of the incision has been developed to proper depth, the scalp is pulled forward with a pair of cat paw retractors and the flap is dissected by reverse cutting with a large blade. This progresses to the point where the base of the flap dissected so far reaches a 45° angle with the zygomatic arches. The trans-sectional arrangement of soft tissues in the temporal area is more complicated.⁸⁷ The frontal branches of the facial nerve leave the parotid gland and cross close to the periosteum of the zygomatic arch into the temporo-parietal fascia, 15–28 mm ventral to the external acoustic meatus.⁸⁸ To protect them, further dissection in the temporal areas must continue under the deep temporalis fascia. The temporalis fascia is incised over the root of the zygoma and the incision progresses firstly through the external leaflet of fascia, just above the temporalis muscle fibers, alongside the base of the developing flap, to the superior temporal line. From here right and left incisions in the temporalis fascia are connected by incising the pericranium between them. The forward dissection of the coronal flap continues in the sub-

Fig. 40.26 Coronal incision. (a) Cutting through skin, subcutaneous layer and galea aponeurotica. (b) Dissection in sub-galeal layer. (c) Hemostasis using Raney's clips.

pericranial level, then subfascial level over the temporalis muscles. The connection between the periosteum and temporalis fascia at the superior temporal line is firmly adherent to the underlying bone and requires sharp dissection, which is best done by cutting diathermy (Fig. 40.27).

At this point it is necessary to consider if a pericranial flap will be needed for anterior cranial fossa repair. If this is the case, its design must be incorporated into the periosteal dissection instead of cutting the periosteum straight across the frontal bone (Fig. 40.28).

When the dissection reaches the orbital margins, careful attention is paid to identification and freeing of the supraorbital neurovascular bundles. This is

Fig. 40.27 Coronal flap dissection. (a) The flap is developed over the vertex of the skull to the line 3–4 cm above supraorbital rims, the incision in the temporalis fascia originating at the zygomatic root is sloping at 45° angle to the zygoma. (b) Incision of the pericranium between superior temporal lines. (c) Dissection proceeds towards supraorbital rims under the pericranium. (d) In the temporalis area the flap is dissected in the subfascial level. (e) The merging between the pericranium and temporalis fascia at the superior temporal line is firmly attached to the skull and must be dissected sharply.

Fig. 40.28 (a) Pericranial anteriorly based flap can be raised over the vertex of the skull. (b) The flap can be used to support the dura mater repair and isolate it further from the paranasal sinuses.

easy if only supraorbital notches are present. If the bundles pass through supraorbital foramina, these must be converted into notches by resecting the foramina's inferior margins with a fine chisel. The periosteum must be subsequently elevated beyond the orbital margin and inside the orbital cavity to allow free retraction of the flap. If more exposure of the nasal skeleton and medial orbital walls is required, the periosteum above the nasal root can be incised vertically (Fig. 40.29).

Closure starts with suturing of the temporalis fascia. This should be very meticulous to prevent facial

Fig. 40.29 (a) Supraorbital neurovascular bundle is encountered at the supraorbital rim. (b) It can be freed from the supraorbital foramen after resection of its inferior margin. (c) Vertical incision of periosteum over the nasal root will facilitate exposure of the nasal bones.

sagging. If the body of the zygomatic bone was widely denuded, the zygomatic periosteum should be supported by suspension sutures applied to hardware or purposely created drill-holes. Next suction drains are introduced under the galea aponeurotica and the coronal incision is closed in two layers: galea and subcutaneous tissue by widely inserted reversed vertical sutures of slow-absorbing Vicryl, the skin by surgical staples. When haemostatic devices like Raney clips are removed from flap margins before closure, some bleeding usually resumes, and this is controlled by bipolar electrocautery.

Limited transcutaneous approaches

Limited transcutaneous approaches use short incisions or stab incisions to insert surgical instruments to manipulate displaced fragments of bone and elevate them to their proper position, where they are supposed to interlock with stable contiguous bone margins. These approaches do not allow visual control of reduction or insertion of osteosynthetic hardware. They are almost exclusively used to reduce zygomatico-maxillary complex fractures.⁷ Sometimes, they are employed in combination with other approaches that allow application of osteosynthesis hardware.

Transcutaneous bone hook or screw

A stab incision is made over the inferior margin of the body of the zygoma on a line dropped from lateral canthus. A sharp bone hook is inserted with gentle pressure until its tip comes into contact with bone. It is then slipped under the bone margin lifting the handle of the instrument at the same time until firm purchase is felt by the surgeon (Fig. 40.30).

Alternatively, a T-bar screw (Carroll-Girard screw), an instrument resembling a corkscrew, is inserted into a drill-hole in the body of the zygoma and used as a handle to manipulate it. A pediatric narrow-flanged nasal speculum is used to protect soft tissues during drilling and screw insertion.

The skin is closed by a single 6/0 monofilament suture.

Gillies approach

A short oblique incision is made in the temporal area above the middle of the zygomatic arch. The incision is deepened to the temporalis fascia and the margins are somewhat undermined. The fascia is incised, taking care not to damage underlying muscle. A suitable instrument, like a Rowe elevator or a strong periosteal elevator, is inserted under the fascia and advanced towards and under the displaced bone fragment (Fig. 40.31).

The wound is closed in two layers: fascia with strong Vicryl, and skin with monofilament or staples.

Fig. 40.30 Transcutaneous bone hook technique. (a) The stab incision is made after palpation of the lower margin of the body of the zygomatic bone. (b) Tip of bone hook is inserted through the incision and brought into contact with the inferior margin of the zygomatic bone. (c) By lifting the handle of the instrument the tip of the hook is driven under the body of the zygomatic bone. (d) The fracture is reduced by traction while palpating the zygomatic arch and orbital margin.

Fig. 40.31 Gillies technique: Rowe's elevator is inserted through a short temporal incision subfascially under the zygoma.

Use of traumatic wounds

Traumatic wounds can sometimes be used for open reduction and internal fixation of midfacial fractures. This applies especially to rare cases of assaults with sharp weapons, which result in long, deep, cut wounds with regular margins and fractures located immediately under the wounds (Fig. 40.32). Lacerations, on the other hand, often do not penetrate all soft tissue layers and can be quite distant from

underlying fractures. Careful judgment is necessary to decide if such a wound can be deepened or extended enough to allow for uncompromised access to the fracture without functional or esthetic detriment.

Because most midfacial fractures are not definitely treated at the time of admission, it is desirable to consider whether facial wounds should be immediately formally repaired or only approximated.

Endoscopic approaches

There is a general trend in many surgical disciplines towards less invasive treatment, avoiding different unfavorable consequences and patient discomfort related to traditional open surgical procedures. Maxillofacial surgery is no exception and endoscopic procedures have become a well established part of therapeutic options in this field. The main advantages of endoscopic approaches in the maxillofacial area are limited incisions and consequent minimal scarring, less damage to vascular circulation, reduced blood loss, avoiding the risk of facial nerve damage, and improvement of intraoperative visual control in areas of limited exposure. In maxillofacial traumatology the main focus has been on endoscopically assisted reduction and fixation of mandibular condylar

Fig. 40.32 (a) Several cut wounds of the face caused by assault with kitchen cleaver. (b) Cut wound of the forehead used to reduce underlying fracture of frontal bone. (c) Repair of inferior orbital rim and floor from another cut wound in the same patient.

fractures which is covered in Chapter 43. In management of midfacial trauma there has recently been development of treatment of orbit, frontal sinus, and zygomatic arch fractures.⁸⁹⁻⁹¹

Endoscopy augments, rather than replaces, general principles of adequate skeletal exposure, accurate fracture reduction, and appropriate internal fixation.⁹¹ The disadvantages of endoscopic fracture repair are

the need for special instruments, more complicated hardware manipulation in limited space, and consequently prolonged operation time.⁹²

Treatment at the site of fracture

Fractures of the maxillary alveolar process

Fractures of the alveolar process are often seen in combination with dental injuries. They are frequently accompanied by changes in the occlusion of the teeth. Hematoma in the vestibulum is often seen. Typically when a tooth in a fractured alveolar process segment is moved, the adjacent teeth in the segment move with it. Bi-manual manipulation will often disclose mobility of a bone fragment. Palpation with a finger placed in the vestibulum over the alveolar process may disclose a step in the bony contour. Fracture of the alveolar socket wall is often seen with lateral luxation of teeth and comminution of the alveolar socket is seen with intrusion of teeth. Radiographic examination will reveal fracture lines involving the periodontal space but extending into the bone beyond the periodontal space.

Dislocated fractures of the alveolar process without involvement of teeth are treated by repositioning and stabilization with osteosynthesis plates. When the alveolar socket is involved by comminution of the alveolar socket or fracture of the alveolar socket wall it is also very important to treat the dental luxation properly. Luxated teeth should be repositioned and splinted. The dental splint is usually also sufficient to treat the alveolar process fracture. Intruded teeth should be left for spontaneous eruption depending on the stage of root formation, and orthodontic traction may be preferred to surgical repositioning for reasons of periodontal healing. For details on treatment of dental trauma see Chapter 39.

Fractures of the maxillary sinus walls

Isolated fractures of maxillary sinus walls result mostly from direct impact, which is always somewhat mitigated by a thick layer of cheek soft tissue. The anterior wall is usually affected. The fracture can have the character of a mere fissure, or can be comminuted and displaced to various degrees. In extreme cases of comminuted fractures the completely detached fragments are found free in the maxillary sinus. Fracture lines sometimes reach the ostium of the infraorbital canal and the infraorbital nerve can be affected. The posterior wall of the maxillary sinus can be broken by the indirect mechanism of transmission of a deforming force through elastic bone. Fracture of the piriform aperture with intranasal dislocation of the fragment can lead to nostril obstruction.

Symptoms

Fracture is usually accompanied by edema and hematoma of the cheek. Anaesthesia of the innervation area of the infraorbital nerve can be present. Intraorally submucosal hematoma may be observed in the upper vestibule. Before development of edema it may be possible to palpate crepitus over the anterior maxillary wall during intraoral examination. There can be bleeding from the nose if blood escapes from the maxillary sinus through the natural ostium of the canalis semilunaris or if the lateral nasal wall and mucosa are injured as well.

Radiographic examination

Plain radiographs, such as as occipitomenal view or orthopantomogram, are not usually suitable for diagnosing fracture lines in thin sinus walls, but they can raise suspicion by detecting the presence of sinus hematoma. On the other hand, axial computed tomography (CT) scans with three-dimensional (3D) or sagittal reconstructions demonstrate even fine undisplaced fracture lines well.

Treatment

Undisplaced or even moderately displaced fractures do not require treatment, because they will not result in observable deformity. Fractures indicated for operation are those with free fragments or with prolapse of soft tissues into the maxillary sinus, and fractures with nasal obstruction.

The fracture is approached by a vestibular incision, the prolapsed soft tissues are reduced, free fragments are removed, and the hematoma is evacuated. Only non-vital mucosal lining is removed from the sinus; no nasal fenestration is done. Fragments big enough to hold screws are repositioned and fixed by micro/miniplates. If this cannot be achieved and the resulting defect would lead to recurrence of soft tissue prolapse, the defect is reconstructed using titanium mesh (Fig. 40.33).

Le Fort I fracture (Guérin fracture, suborbital maxillary fracture)

This fracture line runs more or less in a horizontal direction and separates the lower part of the maxilla, the horizontal plates of the palatal bones, and the inferior one third of the pterygoid processes of the sphenoid bone from the rest of the cranium. The nasal septum is also fractured or dislocated from its maxillary attachment. There can be interfragments along the fracture line. The main fragment is usually dislocated dorsally and its anterior part is also dislocated cranially, where it can become wedged, leading to anterior open bite and/or reverse overjet. Alternatively the whole segment can become loose and drooping with gravity leading to elongation of the middle facial third.

Symptoms

Aside from above-mentioned occlusal disturbance, the upper dental arch can be mobile; however it is sometimes wedged in a pathologic position and cannot easily be moved. In cases without wedging, the maxilla can descend under gravity on mouth opening. Steps can be palpated intraorally on the anterior maxillary wall before edema obscures them. Hematomas in the upper vestibule and epistaxis are frequent.

Radiographic examination

Orthopantomogram can detect Le Fort I fracture, especially if the pyriform aperture, zygomatico-alveolar crest and pterygomaxillary suture are carefully examined. CT scanning (coronal slices and 3D reformatting) offers superior imaging (Fig. 40.34).

Treatment

The purpose of treatment is to re-establish proper positioning of the maxilla with the upper dental arch and to achieve preinjury occlusion, as well as anterior projection of upper lip and anterior facial height.

Fig. 40.33 (a) Comminuted fracture of anterior maxillary wall: defect after debridement of small fragments. (b) Maxillary sinus wall reconstructed with titanium mesh.

Fig. 40.34 Le Fort I fracture: 3D CT reconstruction. Note posterior displacement of the central fragment.

Historically, these fractures were treated by closed reduction and maxillo-mandibular fixation supported by internal wire suspensions or external fixators.⁹³ This mode of treatment usually restored occlusion, but the vertical position of the maxilla was compromised, leading to shortening of the middle facial third. This problem had already been recognized in the preminiplate period, and jig-saw puzzle reconstruction with interfragmentary wiring and bone grafting if necessary was recommended.^{1,13}

Today the leading tenet is reconstruction of the vertical maxillary buttresses. Two of them (paranasal and zygomatico-alveolar) are surgically accessible, so that four supporting struts can be repaired. This will

re-establish proper maxillary position in all three dimensions.

The surgery commences with application of arch bars on both dental arches. Then the maxilla is exposed by bilateral upper vestibular incision. Under visual control the maxilla is mobilized by wire traction on an arch bar, bone hook, or Rowe-Killey desimpaction forceps if necessary. Maxillo-mandibular fixation is secured in correct occlusion (mandibular fractures being repaired first) and the whole complex is rotated cranially with the mandibular condyles properly seated. In non-comminuted cases this maneuver will result in precise reduction of the buttresses that can be plated (Fig. 40.35). In comminuted

Fig. 40.35 Le Fort I fracture. (a) Coronal CT scan; note superior displacement of the fragment with comminution of fracture lines and linear fracture of hard palate. (b) Anterior open bite in the same patient. (c) Osteosynthesis of zygomatico-alveolar, paranasal, and sagittal fracture lines with titanium miniplates. (d) Normal occlusion after treatment. (e) Postoperative panoramic radiograph.

cases the buttresses should be reassembled or grafted.⁹⁴ If a small defect up to 5 mm exists, it can be bridged by miniplate. The need for bone grafting is extremely rare.

Fractures without displacement or with minimal displacement can heal spontaneously,⁹³ but must be supervised. The precondition is a non-comminuted nature of the fracture, because otherwise the facial height could be decreased by gradual impaction of a large fragment by function of masticatory muscles.

Fractures of the hard palate

Fractures of the hard palate are infrequent. They are found in less than 10% of patients with midfacial fractures.⁹⁵ They practically never occur in isolation and are usually part of alveolar process fractures or more complex midfacial fractures of the Le Fort type.⁹⁶ The rare exceptions are isolated fractures of the posterior margin of the palatal bone in young children due to falls on foreign bodies held in the mouth at the time of the accident.

Fracture patterns

The most often encountered fracture of hard palate is a component of alveolar process fracture. It begins interdentally, encircles an alveolar segment and either returns to the alveolar crest (in the incisor–canine area) or runs towards the posterior palatal margin (in the premolar–molar area).

A sagittal palatal fracture splits the hard palate and anterior alveolar process in the midline. It is found in children and adolescents, whose sagittal palatal sutures have not yet ossified.⁹⁷ A parasagittal palatal fracture is usually found in adults with a fully ossified midpalatal suture. It can start anywhere between the canines, either from the interdental septum or through the alveolar socket. In such cases, the involved tooth is usually luxated or avulsed. The fracture line travels posteriorly just next to the palatal crest and can reach the posterior margin of the palatal bone or deviate towards the maxillary tuberosity. Both sagittal and parasagittal fractures naturally involve the pyriform aperture. Some authors also recognize a variant of this fracture pattern: the para-alveolar palatal fracture, which runs further from the midline, close to the palatal base of the alveolar process.⁹⁵

A transverse palatal fracture runs in a coronal plane and divides the hard palate into anterior and posterior parts. It is rarely diagnosed, because it is mostly undisplaced. A complex palatal fracture combines the above-described fracture lines in an unpredictable fashion and is found only in the most severe midfacial injuries.

Symptoms

It must be remembered that palatal fractures, with the exception of alveolar process fractures, are almost

invariably associated with complex midfacial fractures, mostly of the Le Fort type.⁹⁶ Among other symptoms of midfacial fractures, suspicion should be raised by soft palate ecchymosis, hard palate mucosa laceration, luxated or missing incisor and split laceration of the upper lip and/or nasal floor. Fractures can be displaced to various extents, which can result in traumatic diastema and lateral crossbite. Fresh fractures show pathologic mobility.

Radiographic examination

A panoramic radiograph together with occlusal intra-oral film can confirm the diagnosis, however these investigations are often unfeasible in severely injured patients. The examination of choice is coronal and axial CT scan.

Treatment

Displaced palatal fractures greatly complicate treatment of complex midfacial injuries. They increase the potential for fracture malalignment, especially in cases of concurrent mandibular body–condyle fractures. In such instance it is very hard to establish the correct width of the dental arches.

In the presence of an intact mandibular dental arch, this can be used as a matrix for upper arch reduction. The fragments are then fixed by arch bar and circumdental wiring. This may be enough for isolated alveolar fractures, but not for sagittal or parasagittal fractures combined with a Le Fort type fracture. Such fractures have a tendency for rotation of fragments outwards and posterior splaying of the upper dental arch.

Proper reduction and fixation of the maxillary parts into full contact and proper axial alignment of teeth is easier in cases where the fracture line is widened only in the anterior part. In these cases the arch bar fixation can be supplemented by miniplate osteosynthesis at the base of the alveolar process just under the pyriform aperture (Fig. 40.36). It is much harder to achieve reduction of posteriorly widened fractures. Digital pressure is usually insufficient and a special instrument (reduction forceps) is sometimes needed to achieve approximation of the fragments (Fig. 40.37). These should be then secured by miniplates, usually inserted through the palatal mucosa laceration, which can be extended and undermined for this purpose (Fig. 40.38). Vertical fracture lines on the anterior maxillary surface are also plated, so that the whole caudal maxillary segment below Le Fort I line is restored to one unit. The treatment then continues with reconstruction of the vertical maxillary buttresses.⁹⁸

Fractures of nasal bones and related structures

Nasal fractures are not only among the most common facial fractures, but also the most frequent fractures

Fig. 40.36 Le Fort I fracture with sagittal split of the palate. (a) 3D CT reconstruction. (b) The fracture line deviates from the midline behind the central incisors and the alveolar process is displaced laterally. (c) Osteosynthesis of zygomatico-alveolar and paranasal pillars with 1.7 mm miniplates; the sagittal fracture is fixed with a 2.0 mm miniplate.

Fig. 40.37 Hayton-Williams clamp can be used to compress laterally splayed maxillary halves.

in general.^{9–11,99} Their incidence is often underestimated, because many of them are not diagnosed at the time of injury. This omission can lead to chronic nasal obstruction, septal deviation, and external deformity requiring secondary corrective procedures.

Less than perfect results of nasal fractures treatment were reported in retrospective studies.^{100,101} It was also noted that approximately 30% of patients with a nasal fracture have pre-existing nasal deformities.¹⁰¹ Preinjury facial photographs should be obtained whenever possible. Photography of the injury is an important part of the documentation,

because it can later give the patient an appreciation of the extent of deformity before surgical intervention.

Fractures of nasal bones

Symptoms

Nasal fracture should be suspected with any midface trauma. The initial main symptoms include epistaxis, nasal obstruction, and external deformity. This is usually obscured by edema developing within a few hours after injury. Earlier nasal obstruction and fracture should be excluded by careful history so as not to confuse present injury with pre-existing deformities. Crepitance or mobility of broken segments on palpation is diagnostic of fracture. The tip of the nose should be pressed postero-superiorly to evaluate the degree of loss of cartilaginous support. Skin and mucosal lacerations, ecchymosis, and hematomas may be also present. More severe fractures are accompanied by eyelid edema, subcutaneous emphysema, periorbital ecchymosis, conjunctival chemosis, and subconjunctival hemorrhage.

A very important part of evaluation is careful intranasal inspection. Intranasal examination should include topical decongestion of the nasal mucosa. It

Fig. 40.38 (a) After reduction of a parasagittal fracture by compression the palatal laceration is used to insert a miniplate. (b) Properly transversally reduced arch is then fixed to upper maxillary part.

should be especially focused on checking for septal dislocation and submucous hematoma.

Radiographic examination

Routine radiographs are presently considered to be financially inefficient and unnecessary.^{101,102} Plain nasal films fail to reveal nearly 50% of clinically evident fractures. Old fracture lines cannot be differentiated from current minimally displaced fractures. Axial and coronal CT scans should be ordered instead, if there is any suspicion of more complicated fracture pattern, like NOE fracture (Fig. 40.39).

Treatment

Unless the patient presents before significant distorting edema has developed, most authors advocate delaying the procedure 3–7 days to allow for recession of the edema. Closed reduction may still be attempted in the first 3 weeks. After 3 weeks the fracture has usually healed and it cannot be easily reduced. In such case corrective rhinoplasty should be delayed 6 months or more to allow for maturation of the scar tissue.¹⁰³

The nose is extremely well sensitively innervated and perfect anesthesia is essential for achievement of a satisfactory result. Most nasal fractures can be managed under local anesthesia and no differences in outcome were found between patients treated under

Fig. 40.39 Comminuted naso-ethmoid fracture; axial CT scan.

general and local anesthesia.¹⁰⁴ Intravenous sedation is a great help in such an instance. However, if any doubt exists about the straightforwardness of the procedure or the level of a patient's cooperation, general anesthesia should be employed. Even if the reduction is done under general anesthesia, the nose is anesthetized using 4% cocaine with 1:100 000 epinephrine-soaked pledgets. This shrinks the nasal mucosa sufficiently to allow adequate intranasal examination and instrumentation.

Closed reduction should always be attempted in patients seen within the first 2–3 weeks post injury, even if they will need subsequent rhinoplasty. Necessary instruments include Asch and Walsham forceps, blunt Boies nasal elevator, intranasal specula, good suction, and a head light. Nasal fractures are reduced by upward and outward pressure with an elevator placed under the nasal bone about 1 cm below the nasofrontal angle. The reduction is controlled and helped by external digital pressure and molding. The Asch or Walsham forceps may be used by inserting one blade in each nostril or by placing one blade in the nose under the nasal bone and the other on the overlying skin. Incomplete greenstick fractures of the septum and nasal bones can account for later deviations and should be completed prior to reduction.

The bony and cartilaginous structures of the nose are intimately connected with the nasal septum. A common mistake in reduction of nasal fractures is to reduce the bony fracture without attention to the septum. Septal fractures are actually present in an overwhelming majority of cases.¹⁰⁵ Reducing the nasal bone fragments first often reduces the septum simultaneously; if not, the Asch forceps is used to gently elevate the nasal pyramid while the displaced septum is manipulated into its proper place.

If the nasal bones are unstable or comminuted, they must be supported with intranasal packing. The authors usually use expandable foam packs with embedded small airway to enhance patient comfort.

The reduced septum may be also stabilized with silastic intranasal splints secured by a mattress suture, or by subperiosteally placed biodegradable membrane.¹⁰⁶ The reduced nose is supported externally by a splint (Fig. 40.40). The packing is removed after 3 days and the splint after 10 days.

If the fracture cannot be managed satisfactorily by closed reduction, the operation should be immediately converted to an open reduction to avert or minimize the need for secondary revision.⁹⁹ Open reduction, as well as septoplasty and rhinoplasty for delayed repair, should be performed only by an experienced nasal surgeon.

If the nasal fracture is a part of a more complex midface fracture pattern, it can best be treated using a coronal flap (Fig. 40.41). After complete circumorbital dissection and release of the supraorbital nerves, the whole bone skeleton of the nose can be exposed, sometimes with the help of vertical periosteal incision over the nasofrontal angle to release tension. The fragments may be elevated into correct position with intranasal instruments and fixed with miniplates. This approach also offers the possibility of primary bone grafting. Another option, employed mostly for delayed treatment or secondary procedures, is midfacial degloving.⁷⁵

Naso-orbito-ethmoidal fractures

Fractures of the nose sometimes do not remain limited to the nasal bones, but extend into adjacent bony structures: the frontal processes of the maxilla, the lacrimal bone, the ethmoidal bone or even the nasal process of the frontal bone. The nasal bones and the frontal processes of the maxilla form a relatively sturdy unit compared to underlying fine, paper thin, bony labyrinth of the lacrimal bones, lamina papyracea, ethmoidal cells, and cribriform and perpendicular plate of the ethmoid. These deeper structures easily yield and telescope on to themselves, thus allowing dorsal displacement of the robust outer frame. Line of such fracture, denominated as NOE fracture, separates the nasal bones from their frontal articulation, continues latero-caudally across the frontal process of the maxilla into the orbit, and runs through the lamina papyracea or lacrimal bone, and further through the orbital process of the maxilla and the inferior orbital margin back to the lateral wall of the nose (Fig. 40.42). Such fracture may be more or less comminuted. With dorsal displacement of the external framework communication between the nose and the frontal sinus can be disrupted. Important

Fig. 40.41 Repair of a nasal fracture through a coronal flap approach.

Fig. 40.42 Naso-orbito-ethmoidal (NOE) fracture; 3D CT reconstruction.

anatomical structures, namely the medial canthal ligament and the lacrimal apparatus, can also be compromised.¹⁰⁷

The fractures can be classified according to degree of comminution and status of the medial canthal ligament:

1. The central fragment is in one piece.
2. The central fragment is comminuted into manageable pieces, the canthal ligament remains attached to a fragment large enough to allow osteosynthesis.
3. The central fragment is comminuted into non-manageable pieces, the canthal ligament is either completely detached or attached to a fragment too small to allow osteosynthesis.

The whole detached complex may be also divided by a parasagittal fracture line and splayed to the sides, so that the nasal bridge is flattened and the canthal attachments are displaced laterally. Both detachment of the medial canthal ligament and its lateral displacement due to dislocation of its attachment lead to pseudohypertelorism and obtuse deformity of the medial palpebral angle.

Treatment

Proper restoration of form and fixation of NOE fractures usually require the wide access provided only by a coronal flap.¹⁰⁸ Wide exposure of the nasal bones and medial orbital walls is enabled by vertical incision of the periosteum over the nasal bridge. An intraoral approach to the paranasal areas of the maxilla or a transconjunctival approach to the inferior orbital rim and infero-medial wall are also often needed.

The central fragment must usually be repositioned ventrally by intranasal manipulation to re-establish projection of the nasal bridge and reconnect it to the frontal bone. Both nasal bones, if split and splayed, must be repositioned and held in the proper angle. The medial canthal ligaments must be restored to their correct position, preferably by exact reduction of their bone attachments. Various miniplates from different manufacturers are available to achieve these goals. The medial orbital walls are usually comminuted, and because the thinness of the lamina papyracea precludes use of any osteosynthesis devices, they must be reconstructed by autogenous bone grafts or implants.

In cases where the medial canthal ligament is detached or attached to an unusable bone fragment, it must be engaged and fastened in its proper position by a procedure known as medial canthopexy. It consists of suturing the ligament with a fine wire suture passed transnasally either to a drill-hole on the opposing undamaged side, or to a cantilevered miniplate. It is necessary to bear in mind that the position of the posterior arm of the ligament is what matters regarding the shape of the palpebral fissure and the position

of the lower lid. Therefore the canthopexy should be positioned deep enough in the orbit. Because canthopexy is a difficult and not very reliable procedure, every effort should be made during dissection to preserve the canthal ligament attachment to a bone fragment that could be stabilized by a mini- or microplate.^{109,110}

Fractures of the zygomatic bone

The zygomatic bones have a prominent position in the midfacial skeleton, making them prone to injury in different kinds of accidents. They are sort of keystones of the lateral facial skeleton, articulating with both calvarial (os temporale, os frontale, os sphenoidale) and other facial (maxilla) bones. These intimate contacts result in the zygomatic bone being only rarely broken in isolation. Fractures of the zygomatic bone usually transgress their strict anatomic limits or at least involve above-mentioned articulations. Fractures of zygomatic bone are present in over 40% of all facial fracture patients and are second only to nasal fractures in frequency.^{26-29, 111}

Fractures of the zygomatic bone are also referred to as fractures of the cheekbone or malar bone, fractures of the zygomatico-maxillary complex, zygomatico-orbital fractures, tripod or tetrapod fractures.⁶⁻⁸

The mechanism of injury is usually direct impact. The energy involved, site of impact, and direction of impact will affect the type of fracture (isolated zygomatic arch versus complex zygomatico-maxillary or zygomatico-orbital), the degree and direction of dislocation, and the degree of comminution.

Fractures of the zygomatic arch

Isolated fractures of the zygomatic arch are relatively rare, because for them to happen, traumatizing impact has to come from a lateral direction. On the other hand, they are frequent as a component of zygomatico-maxillary or Le Fort III fractures,¹¹² and are mostly caused by an indirect mechanism: displacement of the body of the zygoma posteriorly, leading to buckling of the zygomatic arch and fracture when the limit of its elasticity is overstepped.

The typical pattern of an isolated zygomatic arch fracture is of the letter M, with two fragments collapsed medially and often impinging on the masseter muscle or even the muscular process of the mandible (Fig. 40.43). Another possible pattern is one with only one site of major displacement, while the distant part of the fragment has just a greenstick fracture, or is only bent (Fig. 40.44).

Symptoms

The patient usually presents with limited or painful mouth opening. There can be visible depression of the facial contour at the fracture site, which later becomes camouflaged by developing edema.

Fig. 40.43 Depressed M-shaped fracture of the zygomatic arch with three fracture lines.

Fig. 40.44 Oblique fracture of the zygomatic arch as a component of a zygomatico-maxillary complex fracture. The zygomatic process of the temporal bone just has a greenstick fracture and is displaced medially. The body of the zygomatic bone, with its temporal process, is rotated.

Radiographic examination

The classical X-ray projection is an axial (submento-vertex) view of the skull. Fracture of the zygomatic arch can be also diagnosed on an occipito-mental view, and on a CT scan. CT examination can however miss this fracture if the slices are not thin enough and coronal scans or reformatting was not done. Ultrasonography is another diagnostic option which has been employed recently.

Treatment

Isolated zygomatic arch fractures are usually reduced by a limited transcutaneous approach, either transcutaneous bone hook reduction or Gillies temporal approach.¹¹³ Transcutaneous bone hook is faster, but less reliable and can lead to injury of the frontal

branches of facial nerve. The authors recommend it only for a fracture located anteriorly, near the body of the zygomatic bone. On the other hand, Gillies approach is safe and highly reliable. The elevator is introduced under the zygomatic arch, which is reduced while palpating and counteracting over-reduction with a finger (Figs 40.31, 40.45).

Open reduction of isolated zygomatic arch fracture is very rarely done, because only very posterior fractures are accessible from relatively easy preauricular incision and coronal incision is not justified in this instance.

Fig. 40.45 (a) Depressed fracture of the zygomatic arch on a submento-vertex radiograph. (b) After reduction achieved through Gillies approach.

Fractures of the zygomatico-maxillary complex (zygomatico-orbital fractures)

Fractures of the zygomatico-maxillary complex (ZMC) are extremely diverse as to direction and degree of dislocation, or number of fragments. Many of these fractures are not displaced and therefore could have been easily overlooked in the past, when CT scans were not available or were not done routinely in all suspected facial fracture cases.

While some of the zygoma's four articulations with other bones can be fully interrupted and dislocated, others can be just of a greenstick character. This is mostly the case of zygomatic arch and fronto-zygomatic articulation. In the case of the widest articulation, with the maxilla, three areas should be considered separately: the zygomatico-alveolar crest, inferior orbital margin, and orbital floor.

The degree of fragmentation of fracture lines has an impact on the precision of reduction and stability of reduced fragments. Unfortunately many ZMC fractures have fragmented margins, especially in the area of the zygomatico-alveolar crest, which is also the most important support of the zygomatic bone in a vertical direction. As a result, the authors are skeptical about attempts to reduce ZMC fractures blindly and without fixation.

Symptoms

Symptoms of ZMC fracture will depend upon sites, type, and degree of dislocation. The most universal clinical finding is edema of overlying soft tissues, which develops during the hours after injury, and can later mask other symptoms or make their evaluation difficult (Fig. 40.46).

If the patient presents immediately after injury with a severely dislocated fracture, he/she can have considerable facial asymmetry and steps can be palpated on the zygomatic arch, inferior and supero-lateral orbital margins, as well as the zygomatico-alveolar crest. The body of the zygoma can be "bodily" dislocated or rotated, but mostly both types of movement

combine. It can cause loss of anterior and/or lateral projection of the zygoma, resulting in a flattened face and asymmetry. Bodily inferior dislocation with separation of the zygomatico-frontal suture will result in a change of position of the lateral canthus and therefore a downward slant of the palpebral fissure in the horizontal plane (Fig. 40.47). Dislocation of the orbital walls can lead to an increase (frequent) or diminution (rare) of orbital volume resulting in enophthalmos or exophthalmos. Limitation of ocular motility may be present either from injury or entrapment of ocular muscles. Because the fracture nearly always involves the infraorbital canal, anesthesia of innervation area of the infraorbital nerve is found in over 80% of patients.¹¹⁴ Bleeding from the nose is common. In cases of severe dislocation of the zygomatic arch or posterior displacement of the body of the zygoma, mouth opening can be limited due to interference with the coronoid process of the mandibular ramus and injury to the temporalis muscle. Orbital hematoma and subconjunctival suffusion usually develop during the first 24 hours.

All patients with ZMC fracture should be evaluated by ophthalmologist,¹¹⁵ not only to evaluate ocular position and motility, but also to exclude concomitant eye injuries, most frequent of which are corneal abrasions. If this examination is not done promptly, it can become increasingly difficult later on due to developing edema.

Radiological examination

Basic skull projections are useless in diagnosing ZMC fracture. An occipito-mental (Waters) view can give some initial orientation, but not full appreciation of the detailed fracture pattern. In the presence of clinical symptoms, a CT scan should always be done, not only axial, but also coronal slices, or coronal reconstructions, if positioning of the patient for coronal scans is not possible due to associated injuries (especially cervical spine injury). Recently, introduction of helical CT scanners that allow for reformatting in any

Fig. 40.46 Edema, periorbital hematoma, and temporal subconjunctival suffusion develop shortly after ZMC fracture.

Fig. 40.47 Downward slant of the palpebral fissure in the horizontal plane as a consequence of displacement of lateral palpebral canthus.

chosen level, has eliminated this problem (Fig. 40.48). 3D reconstructions are extremely helpful for appreciation of the type and degree of dislocation (Fig. 40.49). Radiological examination should answer the following questions:

1. Which articulations are dislocated and which only bent?
2. Is there any comminution of fracture lines?
3. Is there a loss of lateral or anterior projection?
4. What is the status of the orbital walls and orbital volume?

In evaluation of dislocations it can be useful to compare fractured ZMC with the mirror image of uninjured side.

Treatment

The goal of treatment is to establish preinjury anatomy and stabilize fragments in their anatomic positions so that the bone healing can take place. While this goal can be accomplished and its accuracy ascertained with relative ease in most facial fractures, in the case of ZMC it can be quite challenging. The reason rests with the 3D complexity of the zygomatic bone and difficulty in accessing some of its facets.

Proper reduction of ZMC fracture should result in precise alignment of six areas: zygomatic arch, supero-lateral orbital margin, lateral orbital wall, orbital floor, inferior orbital margin, and zygomatico-alveolar crest. Theoretically alignment of any three points of a 3D structure should result in other areas being aligned as well. However, some of these areas tend to

Fig. 40.48 CT examination of comminuted ZMC fracture. (a) Displacement of lateral orbital wall with interfragment. (b) Comminution of walls of maxillary sinus and depressed M-type fracture of zygomatic arch. (c) Depression and medial displacement of body of zygomatic bone, comminution of maxillary sinus wall, trap-door fracture of orbital floor. (d) Bone fragment impinging on lateral rectus muscle.

Fig. 40.49 3D CT reconstruction gives a good idea about the overall fracture pattern and type of dislocation but is insufficient for evaluation of the internal orbit. (a) Posterior rotation of the zygomatic body. (b) M-type fracture of the zygomatic arch.

be comminuted, making them unsuitable for verifying proper overall zygoma position. They are mostly the inferior orbital margin, the orbital floor, and also very often the zygomatico-maxillary crest. Other areas are rarely comminuted, but are accessible only through time-consuming coronal incision. They are the zygomatic arch and the lateral orbital wall. The last area, the zygomatico-frontal suture, is easily accessible and rarely comminuted, but it is also the least reliable indicator of proper reduction, often being the pivotal point around which the whole complex rotates. Minor dislocation here can result in major discrepancies in distant fracture lines.

After proper anatomic reduction the question of adequate fixation arises. This has been a controversial topic for a long time.¹¹⁶ Before introduction of miniplate osteosynthesis, ZMC fractures were mostly treated by the Gillies approach or transcutaneous bone hook reduction and surgeons relied on interlocking of fracture lines for fixation. In cases of unstable fractures, a wire suture was employed, and comminuted fractures were supported by external pin, antral strut, packing or balloon. Immediate radiological verification of proper reduction was usually not done. Subsequent post-treatment deformities used to be ascribed to postreduction dislocation of the zygomatic bone by the pull of the masseter muscle. However it can be argued that perhaps proper reduction was never achieved, which fact became obvious only after edema had completely subsided several weeks later.¹¹⁷ Even now some authors consider postoperative X-ray examination unnecessary¹¹⁸ in contrast with other reports¹¹⁹ on intraoperative CT imaging leading to immediate correction of unsatisfactory reduction of fracture.

Currently the need for stable fixation of the majority of ZMC fractures is recognized, with the exception of fractures without comminution of any fracture line. The number of sites that need to be plated and the strength of applied hardware, however, are still a matter for disagreement. The recommendations vary

from “minimized treatment” by single miniplate¹²⁰ to plating every accessible fracture line.¹²¹

Another controversy regards orbital exploration. Again various authors differ widely in their recommendations, from routine orbital exploration to orbital exploration only done in “cases of primary diplopia”.¹²⁰ Orbital walls are involved to some degree in every true ZMC fracture. This involvement varies from a simple fracture line resembling a crack to complete disruption with soft tissue prolapse, where the need for exploration and repair is obvious (Fig. 40.50). It is important to think not only about the pretreatment situation, but also about what happens to orbital walls during reduction. In most cases a simple orbital fracture, although dislocated, will be reduced together with other fracture lines even without orbital exploration.¹²² In some cases, however, the reduction maneuver can lead to soft tissue entrapment or further fragmentation and resultant insufficient reduction and restoration of orbital volume.

It is obvious from previous considerations that ZMC fractures differ widely in severity and different treatment approaches are necessary for their rational and successful management. Fractures without any comminution and without other dislocation than *ad axis* (fragments must remain in contact) in areas of the zygomatic arch and zygomatico-frontal suture can be treated by closed reduction (transcutaneous bone hook, screw or elevatorium through Gillies approach). If the fracture is unstable after reduction or cannot be reduced, the authors use an intraoral approach first to obtain reduction and stabilize the fracture by plating the zygomatico-alveolar crest. The intraoral approach is an obvious choice, because it has minimal morbidity and leaves no visible scar. The zygomatico-alveolar crest is a good place to evaluate reduction and apply a miniplate, which will act against the masseter pull and prevent tilting of the zygomatic bone downward and inward.¹²² Reduction at the inferior orbital margin can also be checked from this approach.

If the infraorbital margin is badly displaced or comminuted, or orbital exploration is required, either conjunctival or sub tarsal incision is indicated. Another option for simultaneous repair of supero-lateral and inferior orbital margins and orbital floor is conjuncti-

val incision with lateral canthotomy, which can provide access to both sites.⁸³ Exploration and repair of three sites is sufficient for precise reduction and stabilization of the majority of displaced fractures (Fig. 40.50).

Fig. 40.50 Moderately displaced fracture of right ZMC. (a, b) Coronal CT scans reveal displacement of the posterolateral maxillary wall, fragmentation of the lateral orbital wall and distension of the zygomatico-frontal suture. Also notice air in the soft tissues of the cheek. (c) The fracture was reduced with a bone hook introduced through an upper vestibular incision. Miniplate osteosynthesis of the zygomatico-alveolar pillar. (d) Miniplate osteosynthesis of the zygomatico-frontal area through a lateral eyebrow incision. (e) Postoperative radio-graph – occipitomental view.

The exception is the displaced ZMC fracture with loss of anterior projection due to either overlapping (*dislocatio ad latus cum contractionem*) or laterally buckling fracture of the zygomatic arch. Such a fracture is usually the result of high-velocity injury and is accompanied by comminution in other sites making precise reduction difficult. In such cases the authors opt for a coronal incision that will provide excellent access to the zygomatic arch and enable its reconstruction and thus proper anterior projection of zygomatic bone.¹²³ Naturally the supero-lateral orbital margin is repaired from the same approach and, if necessary, the lateral orbital wall can be exposed after stripping the anterior attachment of the temporalis muscle to assist in the precision of the reduction.

Reconstruction of the orbital floor is mandatory in all cases of comminution, soft tissue prolapse to the maxillary antrum or increase in orbital volume. The authors' preferred material for this reconstruction is titanium mesh (Fig. 40.51). A detailed discussion of orbital repair is provided in Chapter 41.

Fractures of the orbit

The treatment of these fractures is covered in Chapter 41 in this book.

Subfrontal fractures

Le Fort II fracture

Fracture of Le Fort II type combines characteristics of the Le Fort I and NOE fractures. If present in bilateral symmetrical form, it resembles a pyramid. The fracture line crosses the nasal bridge, runs through the fronto-maxillary suture area into the orbit, continues posterior to the medial canthus attachment across the medial orbital wall to the orbital floor and from there leaves the orbit on its inferior margin near the zygomatico-maxillary suture to continue along this suture to the pterygo-maxillary suture (Fig. 40.52). Lower parts of the pterygoid processes of the sphenoid bone are broken off and attached to the central fragment.

Fig. 40.51 Severely displaced ZMC fracture with loss of lateral and anterior projection. (a) Coronal CT scan reveals narrowing of left orbit, medial displacement of body of zygomatic bone and collapse of zygomatico-alveolar pillar. (b) Axial CT scan showing severe posterior and medial displacement of zygomatic bone with fragmentation of anterior and postero-lateral maxillary walls. (c) Exposure through an upper vestibular incision: fragmentation and collapse of zygomatico-alveolar buttress. (d) Exposure through sub tarsal incision: comminution of inferior orbital rim. (*cont'd*)

Fig. 40.51 (cont'd) (e) Exposure through upper blepharoplasty incision: infero-medial displacement of frontal process of zygomatic bone. (f) Reconstruction of zygomatico-alveolar pillar. (g) Inferior orbital rim and orbital floor reconstructed with titanium mesh. (h) Reduction and miniplate fixation of fronto-zygomatic fracture. (i) Defect of maxillary sinus wall repaired with titanium mesh. (j) Postoperative radiograph – occipitomental view. (k) Postoperative panoramic radiograph.

The fracture can be dislocated to various degrees, mostly dorso-cranially, like the Le Fort I fracture. This results in similar occlusal disturbance. Due to the upper component of fracture the nasal bridge is deformed and the medial and inferior walls of the orbit are disrupted.

Not infrequently the Le Fort II fracture is combined with a sagittal or parasagittal fracture of the hard palate.

Symptoms

Patients regularly present with nasal bleeding and eyelid edema and suffusion. Palpation of the nasal bridge and inferior orbital margins may reveal a step or crepitus. When the edema subsides, patients with major displacement can have a depressed central facial area – so-called dish face. Intraorally there is edema and hematoma in the upper vestibule and anterior open bite. Steps can be palpated on the zygomatic

Fig. 40.52 Le Fort II fracture combined with left NOE and ZMC fracture. (a, b) 3D CT reconstructions show the pyramidal pattern of the maxillary fracture, comminution of the left medial orbital wall, undisplaced fracture of the left frontal bone, temporal bone and zygomatic arch; note displacement of the maxilla with anterior open bite. (c) Post-treatment OPG showing reconstruction of four maxillary buttresses, as well as inferior orbital rim. (d) Normal occlusion after treatment.

matico-alveolar crests. The upper dental arch may be mobile, and during its manipulation pathologic movement may be palpated over the nasal bridge and inferior orbital margins. However, more often than in Le Fort I fracture, the central fragment is firmly wedged in its new position and cannot easily be moved.

Radiological examination

CT scans, both coronal and axial slices, are necessary to fully evaluate the whole extent of fracture. 3D reformatting is extremely useful for overall appreciation of the fracture pattern.

Treatment

As in Le Fort I fractures, the key to proper reduction is occlusion, therefore treatment commences with

application of arch bars followed by mobilization of the central fragment. This can be quite difficult, because of the great complexity of the fracture line and the inaccessibility of some of its areas. Use of disimpaction forceps is frequently unavoidable. Proper mobilization is crucial for restoration of anterior facial height and prevention of postoperative anterior open bite. When passive positioning of the maxilla is not possible, a concomitant osteotomy may be the last resort to restore proper occlusion.¹²⁴

After the central fragment has been fully mobilized and central occlusion secured by maxillo-mandibular fixation, fracture lines are exposed from intraoral and lower eyelid approaches and the whole complex is rotated cranially with the mandibular condyles properly seated. This should result in alignment of the zygomatico-alveolar crests and infraorbital margins,

which are consecutively plated. In the absence of gross comminution there is no need to expose the nasal bridge that will be satisfactorily reduced. If there is comminution of NOE complex, it must be repaired through a coronal approach. Orbital walls should be explored in such a case and any large defects resulting from the fracture or its reduction should be repaired.

Le Fort III fracture

Fracture of Le Fort III type is sometimes also referred to as craniofacial separation, because it effectively separates the midfacial skeleton from the neurocranium. The fracture line divides the nasal bones and spina nasalis of the frontal bone, breaks the nasal septum, crosses into the medial wall of the orbit behind the posterior lacrimal crest, continues through the orbital processes of maxilla and zygomatic bone into the inferior orbital fissure, separates the zygoma from the ala major of the sphenoid, and runs through or next to the frontozygomatic suture. Separation is completed by fracture of the zygomatic arches and pterygoid plates of the sphenoid bone well above the pterygo-maxillary suture.

The pure pattern of the Le Fort III fracture is found only in a minority of cases; the midfacial complex is usually comminuted to some extent and other fracture patterns, like Le Fort I or Le Fort II, ZMC fracture or NOE fracture can be also identified. The fracture can be also complicated by paramedial split of the maxilla and palatal bone.

Symptoms

Patients quickly develop typical balloon-like edema of the face, binocular eyelid hematomas, and subconjunctival suffusions (Fig. 40.53). Nasal bleeding is common. The midfacial complex can be displaced to different extents, which can result in occlusal disturbance, usually anterior open bite and/or reversed

Fig. 40.53 Facial appearance of patient with Le Fort III fracture.

overjet. On manipulation with the dental arch, pathologic movement can be elicited and palpated over the nasal bridge and supero-lateral orbital margins.

Radiographic examination

Basic skull projections are useless in detection of this type of fracture. Only the occipito-mental (Waters) view of the skull can discover bilateral disruption of the zygomatic arches and superolateral orbital rims. Axial and coronal CT scans with 3D reconstruction are necessary to evaluate fully the pattern of the fracture, especially the extent of disruption of the fronto-nasal area.

Treatment

Restoration of proper occlusion is one of the main aims of treatment, therefore arch bars are first applied to the dental arches. Surgical access is through coronal incision that provides unimpeded exposure of all areas of alignment and osteosynthesis: zygomatic arches, supero-lateral orbital rims and fronto-nasal suture (Fig. 40.54). The midfacial complex must be properly reduced and this requires its mobilization via use of disimpaction forceps and intermaxillary fixation. Concomitant mandibular fractures are reduced and plated first. The maxillo-mandibular complex is then rotated cranially with properly seated condyles until full contact is achieved with the cranial base. At least the zygomatic arches and supero-lateral orbital rim should be plated. The frontonasal area is a less important fixation point because of inherent weakness of the underlying NOE complex, which often leads to comminution.

Fractures of the frontal bone

The squama of the frontal bone formally belongs to the neurocranium and forms underlying skeletal support of the upper facial third. However from a practical point of view the frontal bone is often involved in midfacial fracture patterns¹²⁵ as it is intimately connected to midfacial structures through the fronto-nasal, fronto-ethmoidal, fronto-maxillary, and fronto-zygomatic sutures. The frontal bone also forms the superior wall of the orbit.

The frontal bone is a strong bone with a double cortical layer and an interstitial, well developed diploe layer. Its weakness is the presence of the frontal sinus, which is developed to variable extent in different individuals. The anterior wall of the sinus can be broken in isolation by a direct mechanism (Fig. 40.55) or it can be broken and displaced together with large fragments. In these cases the posterior wall of the sinus is broken and displaced to the same degree (Fig. 40.56). However the posterior wall can be sometimes affected more than the anterior wall, or even fractured while the anterior wall remains intact. This phenomenon is explained by elastic deformation of bone and transmission of the traumatic force to the thinner posterior sinus wall. (Fig. 40.57).

Fig. 40.55 Fracture of anterior wall of frontal sinus. Coronal CT.

Fig. 40.56 Severely displaced frontal bone fracture involving both anterior and posterior walls of frontal sinus. Coronal CT.

Symptoms

Frontal bone fractures are mostly caused by high-velocity mechanisms and consequently are often accompanied by intracranial injuries, such as brain commotion and contusion or intracranial bleeding, which can lead to alteration of consciousness.

Locally bruises, excoriations or lacerations can be seen. There is often bleeding from the nose. Gross displacement of fragments can lead to forehead deformity (Fig. 40.56), which is later masked by developing edema. Displaced fractures can be accom-

panied by disturbance of sensitive innervation in the areas of the supraorbital and supratrochlear nerves. Orbital ecchymosis and subconjunctival hematomas develop if the fracture extends into the orbital walls. In such cases damage to orbital structures and variety of related ocular symptoms may be present. Dislocated fractures are frequently associated with dural tears, which may or may not result in nasal cerebrospinal fluid (CSF) leak. Close cooperation with the neurosurgeon and ophthalmologist is therefore of utmost importance.

Fig. 40.57 Infrequent case of posterior wall of frontal sinus fracture with anterior wall intact.

Radiological examination

For a fully conscious patient with suspected skull fracture, basic X-ray projections of the skull may be sufficient. If the patient is unconscious or basic projections have roused suspicion of fracture, a CT scan of the brain and skull should be performed.¹²⁶ Axial slices give a good picture of the anterior and posterior walls of the frontal sinus, but coronal scans or reconstructions are necessary to evaluate the orbital roof and medial wall, and the fronto-nasal area. Coronal scans can also detect fractures of the cribriform plate of the ethmoidal bone, which usually run in an antero-posterior direction. In the case of comminuted fractures it is very useful for treatment planning to have 3D reconstruction.

Simple frontal bone fractures

Simple frontal bone fracture means fracture without displacement. For practical purposes, fractures with displacement less than the thickness of the outer or inner cortical layer are regarded as undisplaced. Because the frontal bone is not a site of attachment of any powerful muscles, there is no risk of secondary dislocation of fragments. The presence of dural tears is also improbable in undisplaced or minimally displaced fractures. Such fractures do not require any treatment except antibiotic cover if frontal sinus hematoma has developed.

Compound frontal bone fractures

Frontal bone fractures resulting from high-velocity injury tend to be comminuted with displacement of fragments that are mostly depressed. Rarely stress forces produced during impact can lead to outward buckling of fragments. Fractures can be associated with lacerations of the skin and underlying soft tissues and can thus communicate through laceration

with the external environment and become contaminated. Sometimes foreign bodies can be found in lacerations or even embedded in the fracture. Displaced fractures involving the frontal sinus must be considered contaminated, even if they do not communicate with any external wound, because of the continuity of the mucosal lining with the nasal cavity. Displacement of fractures intracranially can result in laceration of the dura mater with CSF leak, either directly through the wound or through the frontal sinus and fronto-nasal ostium to the nose. Rarely brain tissue can prolapse into the frontal sinus. Perforation of the dura mater violates the anatomic barrier preventing spread of infection from the nose and paranasal sinuses intracranially. If not repaired, whether or not there is a continuous CSF leak, the patient is at life-long risk of intracranial infectious complications like meningitis, encephalitis or brain abscess.¹²⁷

The frontal sinus is lined with respiratory mucosa containing mucinous cells. Therefore there is a potential for mucus retention and development of mucocele if the drainage of the sinus into the nasal cavity has been interrupted by displaced bony fragments.¹²⁸ Consequently, in such situations, drainage should be either restored or the sinus should be eliminated.

Treatment

Treatment of compound frontal bone fractures has four goals:

1. To seal dural perforations and isolate the intracranial space from potential sources of infection.
2. To ascertain patency of the fronto-nasal ostium, or to eliminate the frontal sinus if this patency cannot be maintained.
3. To restore the integrity of the frontal bone so that the brain is sufficiently protected from future insults.
4. To restore the contour of the forehead.

The fractured frontal bone is exposed via a coronal flap. During its dissection it is necessary to consider whether a pericranial flap will be required and proceed with a pericranial incision accordingly. If the frontal bone fracture is a component of a more complex midfacial fracture and some periorbital incisions are needed for repair, these should be performed first, before a surgical periorbital edema develops. Only in exceptional cases can an existing traumatic wound be used to address an isolated fracture of the anterior frontal sinus wall.

If only the anterior wall of frontal sinus has been broken and displaced, fragments can usually be lifted and removed with a pointed periosteal elevator. This makes the sinus cavity accessible for revision and debridement. Blood clots, loose bone fragments, and non-viable tatters of mucosa are removed, while healthy sinus mucosa is preserved. Consequently the fragments are reassembled, repositioned, and

Fig. 40.58 Exposure of frontal bone fracture through coronal incision. (a) The supraorbital nerves were dissected free from the supraorbital foramina. Minor irregularities are smoothed by a large bur.

stabilized with titanium plates or mesh and screws (Fig. 40.58).¹²⁹ Some trimming of fragment margins may be necessary to achieve reduction. Fragments too small to be engaged by hardware are discarded. Resulting gaps can be easily reconstructed with titanium mesh or left alone if not larger than 5 mm.¹³⁰

In cases where the full thickness of the frontal bone has been broken and displaced, fragments can be safely lifted only if buckled out. Attempts at prying out impacted full-thickness fragments can lead to further dural laceration, sagittal sinus or even brain injury. In such a situation low bi-frontal craniotomy encircling the whole fracture pattern is necessary. This provides wide access to the floor of the frontal sinus, the frontonasal ostium and the orbital roofs. It also enables the neurosurgeon to perform careful revision and repair of the dura mater of anterior cranial fossa. Craniotomy is also necessary in rare cases of displaced fractures of the posterior sinus wall without anterior wall involvement.

Management of injured frontal sinus and fronto-nasal ostium

Restoration of patency of the fronto-nasal ostium was traditionally attempted by insertion of a transnasal tube into the sinus, which was kept in place for several weeks or even months to serve as a stent for healing and re-epithelization.¹³¹ Results of such attempts were, however, often reported as disappointing due to scarring and resulting stricture of the neo-formed communication. On the other hand there are recent reports that the regeneration capacity of mucosal lining is sufficient to keep the communication patent even without stenting, if the bone frame was anatomically reduced.^{132,133}

Elimination of frontal sinus can be achieved by either obliteration or cranialization.^{126–130} In the case of obliteration, the mucosal lining of the sinus must be completely removed and peripheral osteotomy of sinus walls performed with a rotational instrument to get rid of microscopic extensions of the mucosa lining

into so-called Breschet pits. Unfortunately this can sometimes be very difficult if not impossible, especially in patients with extremely pneumatized sinuses that can extend far into the orbital roofs. These extensions are narrow and have egg-shell thin walls making the above described procedure unfeasible. After proper mucosal debridement the resulting cavity is filled by autogenous material: bone, muscle, fascia or fat grafts were used for the purpose. Again, in cases of extremely pneumatized sinus the necessary amount of material can be a hindrance. The large body of non-vascularized material can become infected. A better option seems to be spontaneous bone regeneration, where only the ostium of the debrided sinus is plugged by a graft and the cavity is left to the process of filling with blood and its subsequent organization and ossification.¹²⁶

Cranialization of the frontal sinus is a method of eliminating the sinus by removing its posterior wall and thus making it an extension of cranial cavity (Fig. 40.59). The cranialization procedure requires craniotomy and is indicated in cases of posterior sinus wall disruption. Naturally the mucosal lining has to be completely removed, including peripheral osteotomy, and the fronto-nasal ostium must be plugged. If dural tear was present, the intracranial space should be further isolated from the nose by an additional layer of vascularized pericranial flap introduced through a lower craniotomy slit.¹³⁴

When reconstruction of the orbital roofs is needed, this must be done before insertion of the pericranial flap. The same is true for reconstruction of the supra-orbital rims and NOE complex. After insertion of the pericranial flap these structures will no longer be accessible. Details of sequencing of panfacial fracture repair will be addressed in Chapter 41.

After completion of above-mentioned steps the fractured fragments and parts involved in the craniotomy are either reassembled on a side table or repositioned into the craniotomy defect in a jigsaw puzzle manner and secured by plates and screws. This can

Fig. 40.59 Comminuted frontal bone fracture with involvement of posterior wall of frontal sinus. (a) Bird's eye view of glabelar area exposed through a coronal incision. Note freed supraorbital nerve and whitish foreign bodies. (b) Exposed dura mater after temporary removal of fragments and cranialization of frontal sinus. (c) Sinus mucosa is completely removed and peripheral osteotomy performed with a large bur. (d) A strip of pericranium is used to obliterate the fronto-nasal duct. (e) A pericranial flap is placed over the obliterated frontonasal duct to provide an additional isolating layer. (f) Reconstruction completed. Small irregularities are covered with bone dust and bur holes are covered with titanium plates to protect the underlying dura mater and brain.

be surprisingly difficult in the presence of numerous fragments, therefore marking of pieces and drawing their layout, or digital photography, is advisable before their removal. Sometimes a considerable amount of bone can be missing, either due to severe comminution or more often due to a previous urgent neurosurgical procedure. Unfortunately some neurosurgeons, who are not regular members of interdisciplinary teams, have a tendency to discard "useless"

bone fragments. The proper thing to do is to keep such fragments that cannot be left in place in a subcutaneous abdominal fat pocket for later reinsertion, of course after proper decontamination.

Larger defects are reconstructed by autogenous calvarial bone grafts or split ribs, smaller defects can be covered by titanium mesh. The coronal flap is then carefully repositioned and sutured in proper layers as described earlier.

Biodegradable screws and plates in management of midfacial fractures

Although titanium miniplates are considered the state of the art osteosynthetic device in craniofacial surgery, some controversy still exists regarding whether they should be removed after the healing period or whether it is safe to retain asymptomatic miniplates and screws until the end of the patient's life.^{135,136} More importantly, some miniplates may become symptomatic and their removal is then mandatory. Removal rates vary widely between 5% and 40%.¹³⁷

Common reasons for removal of miniplates include palpable or visible hardware, loosening of screws, pain, infection, wound dehiscence with exposure of hardware, and secondary corrective procedures.¹³⁸ In the mandible, the main reasons for removal are infection and exposure, but in the midface it is visibility, especially in the zygomatico-frontal region.¹³⁹ Moreover special attention is given to removal of metallic hardware in children, in whom it is considered to be a possible factor influencing facial growth. Due to remodeling processes, miniplates become buried in sites of bone apposition and their later removal can be extremely difficult, if not impossible.

Another important factor is ease of accessibility of some application sites. Intraorally introduced miniplates can be removed without considerable morbidity even under local anesthesia. Removal of periorbital miniplates can be more problematic, where repeated surgical access can lead to unfavorable scarring. The most difficult situation arises if the zygomatic arch or the frontal bone miniplates need to be removed. This requires repetition of exposure via a coronal flap, if the hardware was not introduced through traumatic wounds and additional scars are to be avoided.

A possibility for avoiding these problems is to use biodegradable osteosynthetic devices that will be eliminated by natural processes of enzymatic hydrolysis and absorption. The history of development of biodegradable osteosynthetic devices goes back to the early 1970s¹⁴⁰ and today most manufacturers of craniofacial osteosynthetic hardware offer their own biodegradable system. An ideal biodegradable implant should have the following properties: adequate strength and rigidity kept for appropriate time after insertion; malleability; no inflammatory or toxic tissue response; full absorption after fulfilling its purpose; acceptable shelf-life; easy sterilization; and, last but not least, reasonable price. So far there are no products available that fulfill these criteria without reservations.

Using biodegradable implants in management of midfacial fractures has no major long-term adverse effects beyond the total material resorption time and complications associated with the biodegradable

material could be considered minor.¹⁴¹ However the authors have identified several limitations. Firstly the implants are bigger than titanium miniplates used in identical indications. This is because of the inferior mechanical properties of biodegradable materials compared with titanium, which are made up for by increased bulk of material. The titanium systems have significantly higher tensile strength and stiffness compared to biodegradable systems.¹⁴² Because holes in the implants are more widely separated, it is sometimes impossible to engage all small fragments of comminuted fracture. The screws lack cutting threads and therefore require tapping. This again makes fixation of small fragments difficult. Screw heads break easily if greater torque is applied. The plates are not malleable at room or body temperature and need heating to adjust their shape. This makes use of tin templates necessary with most systems. Plates and screws are transparent and therefore poorly visible in operating fields. This altogether leads to elongated operation time.

Currently the authors consider biodegradable plates especially suitable for fixation of non-comminuted frontal bone fractures and orbital reconstruction.^{143–144}

Surgical technique

After proper exposure and reduction of the fracture, the tin template of shape corresponding to the chosen miniplate is adapted to the bone surface by finger molding (Fig. 40.60). The miniplate and template are then held together at one end by a dedicated pair of tweezers and immersed in a bath of sterile water heated to the temperature recommended by the manufacturer (usually between 50 and 60°C) for the recommended time (about 20–30 seconds). After removal from the bath, the plate and template are held in the open air so that the template is lower and the softened plate can assume the template's shape by drooping along the curvature of the template. The fall in temperature will make the plate rigid again. If the shape of the plate is not satisfactory, the procedure can be repeated a limited number of times. A final small adjustment can be made in the site of application with pressure from a heated molding pen. Drill holes are then created by a slowly rotating burr and a tap is used to cut threads in the bone. Screws are inserted using a screwdriver with a torque-limiting device to prevent the screw head being twisting off.

Recently a method has been introduced where resorbable pins inserted in the bone are welded to the resorbable plates using ultrasonic welding.¹⁴⁵ The polymer is anchored in the bone without the need for tapping in the bone. It is claimed that besides shortening operating time this method also results in better stability because all the structures are welded together into one piece.

Fig. 40.60 Use of biodegradable miniplates in frontal bone fracture repair. (a) Clinical appearance of patient with marked deformity of supraorbital rim and upper eyelid edema. (b, c) Coronal CT scans showing depression of anterior wall of frontal sinus and soft tissue emphysema. (d) Fracture exposed through coronal incision. (e) Fragments temporarily removed to allow inspection of the frontal sinus and frontonasal duct. (f) Biodegradable miniplate is held together with template that was molded in fracture site. (g) Bath of hot sterile water softens the miniplate and allows it to assume the shape of the template.

Strategy of management of complex midfacial fractures

In this section general principles are described. The treatment of panfacial fractures is described in Chapter 41.

Timing of repair

There is no doubt that earliest possible repair of any injury, within a time frame of the first 24–48 hours

gives superb results and shortens the period of distress and suffering of a patient. This is easily achievable in simple injuries like facial lacerations, dentoalveolar injuries or even uncomplicated mandibular fractures; the patient must be medically fit, without any other injuries and the treatment facility must be well equipped, staffed, and organized for around-the-clock full performance. In practice all these conditions are only rarely met and comprehensive treatment of midfacial fractures, including those that are not complicated, often has to be postponed and staged.

Fig. 40.60 (cont'd) (h) Template and miniplate after cooling. (i) Bone fragment fixed to miniplate on side-table. (j) Completed reconstruction. (k) Appearance of patient 1 month after surgery.

The following factors can preclude early management of midfacial fractures:

1. Concomitant life-threatening injuries, such as brain trauma, spine trauma, chest trauma, intra-abdominal bleeding, etc., which must be treated first, or which dictate postponement of surgical treatment.
2. Unavailability of necessary preliminary consultations (neurosurgeon, ophthalmologist).
3. Unavailability of full preoperative diagnostic imaging.
4. Unavailability of complete maxillofacial surgery team.
5. Unavailability of operation room or anesthesiologist (in smaller hospital usually occupied by urgent cases like appendectomies or Caesarean sections).
6. Unavailability of special equipment, e.g. osteosynthesis sets that were used in elective cases and are not yet resupplied and sterilized.
7. Underlying medical conditions requiring further investigations or compensation (diabetes, ischemic heart disease, blood disorders, etc.).

If the “golden period” of the initial hours after injury cannot be used for any reason, the developing post-traumatic edema makes some procedures difficult or even unfeasible (full eye examination, conjunctival or eyelid incisions). In such an instance it is better to

postpone definite treatment for several days until all conditions are favorable for successful and uncomplicated surgery.

Most authors agree that midfacial fractures can be treated without significant detriment to the result during the first 2 postoperative weeks. After that mobilization of fragments and their proper positioning become increasingly difficult due to callus formation and soft tissue scarring and contraction. After 3 weeks primary treatment is mostly impossible and surgical correction must be planned as a secondary reconstructive procedure. In such cases it is often preferable to postpone reconstruction for several months until there is maturation of calluses and scars and full recovery of patient's general condition. The usual reasons preventing primary treatment of midfacial fractures are brain injuries, cervical spine fractures, and nosocomial infections with multiresistant bacteria acquired during a long stay in the intensive care unit.

Anesthesia and airway management

Oral and nasal intubation

The usual way of securing the airway during surgical procedures is standard orotracheal intubation. This method can be employed in cases of limited midfacial trauma like ZMC fractures, NOE fractures, or frontal

bone fractures that do not require maxillomandibular fixation (MMF). However in cases of midfacial fractures involving occlusal disturbance, it is necessary to be able to bring the jaws into occlusion and repeatedly check the occlusion intraoperatively for adequate reduction. The same holds for cases with concomitant mandibular fractures.

In most maxillofacial trauma cases the airway is therefore secured by nasotracheal intubation (NTI) without interfering with MMF and the surgical approach.¹⁴⁶ Unfortunately, surgical reconstruction in patients with midfacial fractures sometimes precludes NTI, or requires switching the endotracheal tube from the nasal to the oral route at certain stages of the operation to make the nose accessible to surgery. This may compromise the airways.

NTI can be also problematic in patients with skull base fractures, potentially creating a communication between the nasal cavity and the anterior cranial fossa. Accidental passage of the tube into the cranial cavity is a very rare but catastrophic complication, dreaded by anesthesiologists.^{147,148}

Tracheostomy

A traditional method for airway control in such cases is tracheostomy. Despite being one of the most common surgical procedures, the tracheostomy has a

complications rate of 14–45% documented in the literature.^{149,150} Complications of tracheostomy include bleeding, injury to adjacent structures, surgical emphysema, pneumothorax or pneumomediastinum, blockage of tracheostomy cannula, displacement of cannula, tracheitis, cellulitis, pulmonary atelectasis, tracheo-innominate fistula, tracheo-esophageal fistula, tracheo-cutaneous fistula, tracheomalacia, granulation, tracheal stenosis, excessive scarring and failure to decanulate. Use of tracheostomy should, therefore, be considered judiciously.¹⁵¹ This is especially true in patients in generally good condition, which would require a tracheostomy only due to nasal intubation not being possible or being contraindicated.

Submental intubation

A method with specific special advantages for complex midface trauma cases is submental intubation. In 1986 Hernández Altermir¹⁵² described an alternative method of endotracheal intubation in maxillofacial trauma patients – submental endotracheal intubation (Fig. 40.61). The method gained wide acceptance and with some modifications is considered an attractive alternative to tracheostomy in the surgical management of selected cases of maxillofacial trauma.¹⁵³ The main consideration in choosing this method is the expected length of the postoperative period requiring

Fig. 40.61 Technique of submental intubation. (a) Large artery forceps is introduced into oral cavity through submental incision. (b) The tube is disconnected from the breathing circuit, the connector is removed, the end of tube is grasped by artery forceps and pulled outside through the dissected canal. (c) The tube is reconnected to the breathing circuit and secured in place by silk suture. (d) Position of the tube intraorally in the paralingual groove.

airway control. Usually the tube is switched back to the mouth at the end of the procedure and the patient is extubated. However some authors report on keeping patients on a submental tube for up to 48 postoperative hours. Submental intubation is contraindicated in patients requiring long-term airway maintenance.

Reported complications include detachment of the pilot balloon or its damage during externalization, damage to the cuff of the tracheal tube, infection of the submental wound, abscess formation in the floor of the mouth, salivary fistula, development of mucocele, and hypertrophic scarring. All these complications are relatively rare and avoidable with meticulous technique.

After the induction of general anesthesia the patient's trachea is intubated orally with a reinforced, spiral embedded, tracheal tube. It is important to release the sealed connector from the proximal end of the tube before intubation, so that it can be easily disconnected during the procedure. Patients already intubated by other types of tubes must have their tubes replaced.

A skin incision about 2 cm long is made parallel to the inferior border of the mandible in the submental area to one side of the midline. The right side is preferred over the left side whenever possible, because it allows better visualization of the position of the tube with direct laryngoscopy. Another incision is made intraorally at the junction of lingual attached gingiva and free mucosa of the floor of the mouth. Both incisions are connected by blunt dissection progressing from the outside to the inside through subcutaneous fat, platysma, deep cervical fascia and the mylohyoid muscle. Next a closed strong curved artery forceps is inserted into the mouth through the dissected canal, lateral to the genioglossus and medial to the digastric muscle.

At this point the endotracheal tube is briefly disconnected from the breathing circuit and the tube connector is removed. The deflated pilot tube cuff followed by the endotracheal tube are grasped by artery forceps and pulled outside in sequence. During this maneuver the tube is fixed in the mouth either manually or with McGill's forceps to prevent slipping from the trachea. The tube is then reconnected and secured to the skin of the submental area by strong silk suture, after verifying the unchanged tracheal insertion of the tube by auscultation of chest and checking the proper intraoral positioning of the tube in the paralingual groove (Fig. 40.61). At the end of the procedure the deflated pilot tube cuff and the tube are pulled back in the reverse order and the skin wound is sutured, while the intraoral wound is left to heal secondarily.

Chapter 41

Orbital Reconstruction and Panfacial Fractures

Marc Christian Metzger, Nils Weyer, Ralf Schön, and Rainer Schmelzeisen

This chapter deals with the challenging surgical procedures of orbital and panfacial fractures. With the aim of restoring function and forms in all dimensions, preoperative planning and anatomic preformed implants must be of the highest standard. Intraoperative data acquisition using cone-beam technology and the combination with imaging fusion of preoperative planning data are replacing navigation procedures. The sequence of treatment is important.

Orbital reconstruction

Introduction

In craniofacial trauma, nearly 40% of cases involve the orbital structures.^{1–3} Fractures of the orbital cavity occur mainly in the orbital floor medial to the infra-orbital groove and the nerve canal. Orbital floor fractures are regularly involved in combination with fractures of the medial wall.^{4–6} Due to the very complex geometry of the bony orbit, proper reconstruction after trauma is very challenging, especially if more than one wall of the orbit is affected. Therefore, the main aim of orbital reconstruction is to achieve

the correct preinjury anatomy of the skeleton. Nevertheless, post-traumatic facial deformities caused by incorrect reconstruction often result in enophthalmus, diplopia, and visual acuity disturbance due to enlargement of the orbital volume. In about 8.5% of treated patients with orbital fractures, a volume enlargement leads to enophthalmus, especially when the deep orbital cone is affected.^{6–8}

Secondary reconstruction of the orbit is necessary when the functional or esthetic result after primary repair is not satisfactory or when primary repair of the orbit was not done. The identification of stable anatomic landmarks in secondary reconstruction is often very challenging because of defects or scarring of the orbit. In these cases, more than one surgical procedure is often needed to get acceptable functional and esthetic results. Due to the complex anatomy, good results are achieved using computer-assisted surgery both in primary and secondary reconstructions. Therefore, a virtual three-dimensional (3D) reconstruction of the orbital cavity is mandatory using DICOM datasets. For the exact anatomic reconstruction of the orbital floor and the medial wall, an individually S-shaped cranio-caudal rise of the orbital floor and a retrobulbar bulge in the posterior aspect of the medial wall remain challenging.^{9,10}

Surgical anatomy

The orbital cavity is a pyramidal space. It is enclosed by bony walls and contains the ocular bulb, the peri-orbital fat, and accessory structures such as nerves and the ocular muscles. The ocular bulb itself occupies only one quarter of the bony orbital cavity. The medial orbital wall lies parallel to the antero-posterior axis, while the lateral orbital wall is inclined at 45 degrees to it. The lateral wall is part of the greater wing of the sphenoid and the zygomatic bone and therefore resists most severe impacts. In the posterior aspect of the orbital cavity there is a gap between the lateral wall and the roof, the superior orbital fissure, leading to the middle cranial fossa. The inferior orbital fissure, situated between the lateral wall and

the orbital floor, leads to the pterygopalatine and the infratemporal fossae. Although the bones of the medial wall are thin, the ethmoidal septa support the bone. In cases of trauma, they dissipate the forces and protect the ocular bulb. In the posterior part of the orbit lies the thicker bone of the sphenoid bone, enclosing the optic nerve.^{11,12}

The orbital roof is in a horizontal plane and separates the orbit from the anterior skull base. In the superomedial aspect of the orbital roof the frontal sinus obtrudes between the cranial and frontal bones. From a clinical point of view, orbital roof fractures often lead to proptosis and exophthalmos.¹³

The orbital floor is concave in the anterior third and becomes convex behind the globe, forming the postbulbar bulge. The bone is paper-thin, especially in the region of the infraorbital groove and at the junction between the floor and the medial wall. The canal containing the infraorbital nerve is normally separated from the floor and lies above the maxillary sinus. The most common site of orbital blow-out fractures is the anteromedial portion. Fractures at the posterolateral portion of the floor often lead to dislocation of periorbital fat into the pterygopalatine fossae.⁴⁻⁶

The orbital rim, derived from the frontal, maxillary, and zygomatic bones is the part of the orbit most resistant to trauma. In the lateral and inferior aspect it is thickest and weakest in the region of the frontozygomatic suture. The rim itself is a useful guide to anatomically important intraorbital structures. The infraorbital fissure lies 20 mm posterior to the orbital rim, the supraorbital fissure is 35 mm from the frontozygomatic fissure. The optic canal lies an average 45 mm from the inferior orbital rim. During surgical procedures, care of structures such as the medial canthal ligament and the lacrimal gland is mandatory. During preparation, the ethmoidal arteries must be identified and coagulated. As no important anatomical structure enters the orbit through the infraorbital fissure, dissection of the periosteum is essential for adequate exposure in managing orbital floor injuries.

Orbital soft tissues

The orbital septum is fixed at the orbital rim and acts as a barrier. In the presence of edema, blood, or infection it causes an unhindered rise in retrobulbar pressure.¹⁴ In this case a proptosis of the globe occurs and may lead to a decrease of microvascular circulation of the retina. If drainage of the retrobulbar space is necessary, the orbital septum is best incised in the lateral aspect, superior or inferior to the lateral canthal ligament.

The conjunctiva is a highly vascular structure. Subconjunctival hemorrhages therefore cease at the margin of the conjunctiva. In the medial aspect the tarsal plates of the conjunctiva are continuous with the medial canthal ligament. The ligament inserts outside the orbital rim on to the frontal process of the

maxilla and the posterior margin of the lacrimal fossa. The lateral ends of the tarsal plates merge with the lateral canthal ligament. It is attached to the frontal process of the zygoma. The integrity of these ligaments is very important from both a functional and an esthetic point of view. Preparation at the frontozygomatic suture and injury at the bony junction therefore lead to a downward sloping palpebral fissure. On the other hand, displacement of the bony attachment of the medial canthal ligament causes a lateral movement and leads to a traumatic telecanthus.

The periorbital fat acts like a cushion for eye rotation. Numerous fibrous septa run throughout the orbital fat. In entrapment of the septa, as is often seen in fractures involving the orbital floor, there is mechanical interference with free rotation of the ocular bulb. The integrity of the septae, the muscular tone of the extraocular muscles, and tissue hydration maintain the antero-posterior position of the bulb. The ocular bulb position changes if the bony orbital volume is altered, as in orbital fractures, resulting in an enophthalmos. Therefore, correct reconstruction of orbital fractures is mandatory to avoid esthetic and functional problems. The most common location of herniation of periorbital fat tissue is posterior into the maxillary sinus. In almost half of the cases, periorbital fat is also dislocated medially into the ethmoid cells.

The rectus muscle originates from a tendinous ring at the optic foramen. The long sagittal axis of the bony orbit modifies the action of the muscles. The medial and lateral rectus muscles move the ocular bulb only horizontally. The superior and inferior muscles, due to their oblique position forwards and laterally, bring about rotation, elevation, and depression of the bulb. Diplopia often follows orbital trauma, due to fractures of the orbital floor or the medial orbital wall. Failure of eye movement is not because of nerve palsy but results from edema, hematoma or even septal or fat entrapment. The maximum limitation of movement is often opposite to the field of action of the affected muscle.

The optic nerve is surrounded by dura, arachnoid, and pia mater. The dura fuses with the periosteum of the orbit. In the majority of orbital trauma cases, loss of vision results from edema or hematoma. Only in a few cases do fractures of the optic foramen result in vision loss.

Surgical approaches to the orbital cavity

Several approaches to the orbital cavity have been described in the literature. Besides the transconjunctival approach, access to the orbital cavity can be gained by subciliary, midtarsal, and infraorbital incisions. Because of the high risk of developing ectropion of the lower eyelid and a visible scar, the surgical approach to the orbital cavity should only be performed using a transconjunctival approach.

Transconjunctival approaches offer several advantages to the patient and the surgeon.¹⁵ It has been described especially for the treatment of orbital trauma.¹⁶ The approach produces no visible scar and therefore reduces the incidence of lower lid ectropion. An incision is made 5 mm posterior to the eyelid ridge in the inferior fornix. The postseptal area, which includes the palpebral conjunctiva and the extension of the orbital fat, is the preferred route for access to the orbital cavity. Following the incision of the periosteum, the basal, inferomedial, and inferolateral regions of the orbital cavity can be accessed.

Depending on the region of the orbit to be approached, an upper blepharoplasty approach is made. The orbicularis oculi muscle is incised and the superior and lateral orbital rim is exposed. The blepharoplasty and tranconjunctival incisions are connected by a subperiosteal dissection. After opening the periorbita, the ocular bulb is retracted to gain better visualization of the orbital cavity. After surgery, the conjunctiva is closed with a running resorbable 8/0 suture. The periorbita and the capsulopalpebral fascia do not need to be closed.

Investigation of orbital trauma

Useful techniques for the assessment of orbital trauma are listed in Table 41.1.

Plain radiography of the orbit can demonstrate bony margins clearly, although fractures of thin bony structures of the orbital walls are often overlooked. Therefore, 3D radiography techniques like computed tomography (CT) scans or magnetic resonance imaging (MRI) are more useful for assessment both of orbital fractures and soft tissue. Advances in imaging techniques, such as multiplanar and 3D reconstruction and 3D models, have opened up a new field of computer-assisted preoperative planning and computer-assisted surgery for orbital trauma and secondary reconstruction. Measurement of bulb position and orbital volume can be done preoperatively and compared with the non-affected side. During the operation surgical results can be compared with the normal side and symmetry can be achieved.^{17–23}

Table 41.1 Assessment techniques for investigation of orbital trauma.

History and clinical examination
Ophthalmological investigation and orthoptic assessment
Measurement of bulb position (Hertel index)
Diplopia assessment
Plain radiographs
Computed tomography (CT) scans
Magnetic resonance imaging (MRI)
Three-dimensional reconstruction and volumetric assessment
Computer-assisted preoperative planning
Surgical findings
Computer-assisted surgery

Diplopia is investigated using a linear light and questioning the patient about separation of two images. Additionally, a Hess chart can give reproducible results of ocular movement.

Complications of orbital trauma

A retrobulbar hematoma may occur rarely (<1%) in midface or orbital trauma, or due to the treatment of trauma. Normally, one or more of the posterior short arteries ruptures resulting in bleeding within the intraconal space. Compression of the remaining posterior short arteries leads to a change in the perfusion gradient of the ocular bulb. The rising venous congestion and edema of the optic nerve results in obstruction of the central retinal vessels. Irreversible damage of the retinal cells occurs after 15–20 minutes of vascular occlusion.

Diagnosis and treatment of a retrobulbar hematoma are shown in Table 41.2. Clinically, decreasing visual faculty and the start of blindness is obvious. Often, pain, diplopia, and ophthalmoplegia are evident. A forward displacement of the iris obstructs the drainage of the aqueous from the anterior chamber leading to proptosis of the ocular bulb. The bulb is tense to palpation with increased ocular pressure on tonometry. The pupil dilates with a lack of direct light reflex.

Medical treatment should start by reduction of the intraocular pressure by dehydrating the patient using a combination of intravenous mannitol (250 mg 20%) and acetazolamide (500 mg). Circulatory spasm and intraorbital edema are treated using high dose of steroids (dexamethasone 4 mg/kg as a bolus, then 2 mg/kg every 6 hours for 24 hours). If conservative treatment fails, preparation for surgery should start. The aim of a surgical procedure is decompression of the intraconal space. It is approached by a four-quadrant incision. The intramuscular septum is divided by a medial and lateral upper and lower eyelid incision and preparation of the intraconal space. Insertion of a drain might be useful.

Table 41.2 Diagnosis and treatment of retrobulbar hematoma.

Diagnosis
Pain
Decreasing visual faculty and onset of blindness
Proptosis
Onset of ophthalmoplegia
Tension of the ocular bulb
Ecchymosis
Dilated pupil
Loss of visual evoked potentials
Treatment
Surgical decompression
Mannitol IV (250 ml, 20%)
Acetazolamide IV (500 mg)
Dexamethasone 4 mg/kg as a bolus, then 2 mg/kg every 6 hours for 24 hours

In the case of severe impact from the lateral aspect of the orbit, the edges of the superior orbital fissure might be approximated causing superior orbital fissure syndrome. Due to compression of the neurovascular structures passing through the fissure, edema of the periorbital tissue occurs with proptosis of the ocular bulb. The third, fourth, and sixth nerves are affected, resulting in complete ophthalmoplegia and ptosis. The direct and consensual light reflexes are diminished or lost. A specific sign might be disturbed sensation at the forehead because of involvement of the frontal branch of the trigeminal nerve. Monitoring of the optic nerve is always mandatory. Where there is an intact optic nerve, a conservative approach is proposed. Partial or complete recovery is reported within 6–12 months. Operative decompression of the superior orbital fissure is controversial.

In an extensive injury of the orbit with extension to the skull base, a carotidocavernous fistula can occur resulting in a rare but serious complication. The internal carotid artery within the carotid sinus is damaged. Clinically, a pulsation exophthalmos is visible. On auscultation, a murmur is obvious over the frontal region. Performance of arteriography confirms the diagnosis. The treatment of choice is embolization or transcranial closure.

Preparation for orbital surgery

In the clinical assessment, symmetry of the eye and the zygoma should be examined in all three planes, from in front, superiorly, and inferiorly. Sensations of the skin around the orbit, especially from the infra-orbital, the supraorbital, and the zygomaticofrontal nerves should be recorded. Patients are asked to bring pretrauma photographs. Preoperative clinical photographs are requested.

Clinical investigations also include an ophthalmological examination to determine visual acuity, visual fields, accommodation, eye movement and double vision, and intraocular pressure.

Regarding radiography, occipitomenal projections might be useful to identify bony trauma and fractures of the orbital rim. Zygomatic displacement is also assessed in comparison to the unaffected side. Nevertheless, 3D techniques like CT or MRI scans are more useful in the diagnosis of orbital trauma. The CT imaging modality has been shown to be the diagnostic technique of choice for demonstrating the complexity of these skull fractures.^{17–23} Multiplanar reconstruction with 1 mm slices provides improved preoperative clinical information and thereby enables accurate preoperative surgical planning.

Computer-assisted surgery in orbital surgery

Computer-assisted surgery (CAS) has proved to be an essential tool for preoperative planning and intraoperative control of the precise reconstruction in craniomaxillofacial trauma.^{24–36} Stereotactic guidance

for intracranial surgery dates back to the early 1900s. Frameless surgical navigation (or CAS) systems were subsequently developed.^{37,38} These CAS systems are in common usage for neurosurgery, endoscopic sinus surgery, and craniomaxillofacial surgery.²⁴

A typical maxillofacial CT data set is in DICOM format when recorded from the CT scanner. It is composed of approximately 150 1 mm, non-overlapping slices, obtained with no gantry tilt. Virtual reconstruction of these images in every slice thickness is possible, but due to the resolution of the available scanners this is not practical.³⁹ Voxels represent the volumetric components of the 3D dataset. Pixels are represented in the slice distance. Ideally the square blocks would have isometric length but due to the edge length (0.3–0.5 mm) of the CT scanner detectors, this is not possible. The third dimension is determined by the table feed which is at least 1 mm and is the limiting factor.^{40,41}

All CAS systems incorporate a computer digitizer to track the location of the patient and instruments in space. Four different digitizer modalities have been designed: optical, electromagnetic, electromechanical, and ultrasound. Only the electromagnetic and optical systems are in common use. Each system has unique registration procedures, advantages, and disadvantages.^{42–45}

After importing the CT dataset, performing the preoperative planning, and generation of a “virtual patient”, a registration process is necessary to integrate the virtual and actual datasets. This defines both the anatomy and the location of the patient in the operating room. The registration process involves identification of specific anatomic landmarks or fiducial markers applied to the patient before obtaining the CT scan. The landmarks or fiducials are then identified on the virtual patient. The fiducials used for registration can be separated into two types: invasive and non-invasive. Invasive fiducial markers (e.g. titanium screws) are rigidly fixed to the skull before the CT scan and remain in place until the procedure is complete. Non-invasive fiducial markers can be subdivided into three types: adhesive markers, dental appliances, and anatomic landmarks.^{36,40,46–49} Both the adhesive markers and the dental appliances must be applied to the patient prior to acquiring the CT dataset, while anatomic landmarks are inherently present.

Preoperative planning

After importing the CT dataset of a trauma patient, several different preoperative planning tools are available depending on the defect (Table 41.3).

Unilateral defects

For unilateral defects of the orbital cavity, mirroring the unaffected side to the affected side is a well known standard procedure. After segmentation of the corresponding area of interest, a mirroring procedure is

Table 41.3 Available virtual planning tools for different trauma.

Planning tool	Trauma
Mirroring	Unilateral defects
Virtual implants/reference skull	Bilateral defects
Individual designing (CAD/CAM)	Bony defects

easy to perform in most 3D modeling software. After this, however, an additional adaptation to the remaining bony structures has to be done, due to the physiological asymmetry of the human skull.^{24–26,50}

Bilateral defects

The mirroring protocol is not possible in defects involving both sides of the skull. Therefore, two possibilities were created in the last few years. The first solution is having a database with segmented atraumatic skulls from other patients which can be imported as a reference skull. After fusion and adjusting the selected skull into the patient dataset, virtual repositioning of the dislocated bone fragments is possible considering the ideal shape of the skull. In addition,

the virtual planning can be exported (STL-format) and printed out via a stereolithographic device or a 3D printer (Fig. 41.1).

The other solution is application of virtual bony spare parts for bilateral defects, where no bony fragments can be repositioned (e.g. orbital floor, medial wall). Standardized implants can be imported into the patient dataset and placed in the area where reconstruction is needed. With regard to the orbital cavity, virtual implants are available which represent the definitive physical implant; this is then inserted during surgery (see later section, Preformed orbital implants) (Fig. 41.2).

Bony defects

CAD/CAM procedures are used when large defects of the calvarium need to be covered by alloplastic material, such as titanium, ceramic implants or peak. Several companies offer the service for producing these individual implants. After sending the patient-specific dataset to the company via the internet, planning proposals are sent back to the surgeon. After approval, the individual implant is produced and sent to the hospital for implantation (Fig. 41.3).

Fig. 41.1 (a) Patient dataset after primary insufficient reconstruction including a dataset of an equivalent unaffected midface dataset (green) after image fusion. (b) Bony fragments after reposition to the ideal position given by the unaffected and fused dataset. (c) 3D model including all segments (color coded) where a reosteotomy has to be done.

Fig. 41.2 (a) Patient CT dataset with severe midface trauma. The mirroring procedure is not possible. (b) Standardized virtual orbital floor implants available in a database. (c) Postoperative control CT dataset after image fusion with the preoperative planning. The two inserted preformed titanium meshes are at the same level as the preoperative planned one.

Fig. 41.3 CAD/CAM planning for reconstructing a frontal bone defect (a), including the orbital roof (b), and the corresponding produced ceramic implant (c).

Material for orbital reconstruction

There is still no consensus on the ideal material for reconstruction of the orbital cavity.⁵¹ In general the material should be easily cut and sized in the operating room, and able to be shaped to fit the orbital contours and retain its new form without memory. It

should allow fixation to host bone by screws, wire, suture, or adhesive.⁵²

Depending on the defect size, lyophilized dura, silastic, polyethylene or polydioxanone sheets, hydroxyapatite blocks, titanium meshes, ceramic inlays, or autogenous bone grafts are recommended.^{2,52-60} Elastic materials are often unable to with-

stand static or dynamic stresses in large defects, are prone to foreign body reaction and implant exposure, and only fibrinous connective tissue remains after resorption, with insufficient bone regeneration.^{2,61–63} The disadvantages of autologous bone grafts are rigidity and the requirement of a donor region. They cannot be flexibly adapted to the individual anatomic situation and morbidity of the donor region occurs. In addition, further resorption and displacement of the implanted grafts often occurs if they are not precisely positioned and fixed.^{64–66} Titanium meshes have been used to connect large defective areas in the internal orbit in order to minimize postoperative displacement and facilitate correction.^{52,60,66} They are biocompatible, rigid enough to cover large defects, and deformable, allowing adaptation to individual anatomy (Fig. 41.4). However, adjusting to the individual anatomic requirements can be time consuming and difficult, especially if the deep orbital cone is affected or scarring renders the identification of stable posterior landmarks difficult.^{67–69}

Preformed orbital implants

Intraoperative 3D bending of titanium mesh for the internal reconstruction of the orbital cavity remains challenging, and navigation-guided control of titanium mesh reconstruction is time consuming.^{24,35} Free-hand placement of titanium mesh or calvarian split grafts is difficult for restoring the vertical height of the reconstruction in the posterior aspect of the orbital floor and medial orbital wall. The anatomical reconstruction of the so-called retrobulbar bulge area is most important to prevent eophthalmos deformity. Stereolithographic models or individual alloplastic implants can be used in these situations.

Spiral CT datasets with a 1 mm collimation/slice thickness are acquired. At a workstation (e.g. Voxim, IVS Solutions AG, Chemnitz, Germany) virtual reconstructions can be performed by mirroring the individually defined 3D segment from the unaffected side on to the defective side, which results in a new sub-volume. The resulting sub-volume file can be exported as an STL object to allow it to be read by CAD/CAM machines. The prepared data file then can be sent to a stereolithographic machine, which selectively polymerizes laser-curable liquid resin layer by layer, resulting in the template.^{31,32} This is an accurate process (error about 0.2%) and the fabrication time for these templates is less than 5 hours. Any cutting to size and adaptation of the titanium mesh that is required can be done on the template by hand. Afterwards it is removed and sterilized before the operation (Fig. 41.5).

However, CT scanning procedures are commonly performed in an axial manner which omits segments located parallel to and in between the scanned layers. Therefore the missing information of the orbital floor leads to formation of pseudo foramina in virtual imaging and in stereolithographic models.

Fig. 41.4 Segmentated postoperative dataset of an orbital cavity (green) treated with a common titanium plate (blue). Not considering the shape of the orbital floor has led to an increase in the orbital volume, because the implant was placed into the maxillary sinus.

Fig. 41.5 Stereolithographic model of a right orbital cavity. With such a model, individual adaptation of titanium mesh is possible.

Furthermore this technology involves higher costs and greater logistic challenges.^{2,30,70}

Efforts have been made to produce standardized anatomic preformed 3D implants for orbital reconstruction. These would enable optimal reconstructions in more centers without having additional devices like intraoperative navigation or intraoperative imaging. First basics were created by analyzing and classifying the human orbital floor.⁷¹ By performing CT data analysis the surface of the orbital cavity could be evaluated and this showed that the variation in the depth of the orbital floor was low amongst patients. By clustering the data, the 95% confidence interval was within 1 mm. Age has no influence on the shape of the orbital wall, once the bony skeleton has matured.⁷² Additionally, the volume and morphology of the orbital cavity were constant and steady after the age of 17 years.^{73–75} The extent and width of the orbital rim is reported to show a strong correlation with the volume of the cavity. Depending on ethnic groups, mean values for the volume can be found in the literature ranging from 20–26 cm³.^{74,76,77} By using these results, standardized orbital cavities could be rebuilt and a new type of three-dimensional orbital implant could be designed (Fig. 41.6).

Only two different sizes are necessary to cover the area of interest in a standardized way at the orbital cavity; these two sizes are available in male and female types. The average implant error was less than 1 mm for all orbits studied.⁷⁸ Anatomic structures and landmarks can be coded in these implants. With

Fig. 41.6 Standardized preformed orbital implant (for patient's left side).

regard to the anatomic reconstruction demands, the following structures determine the implant borders: anterior – lower orbital rim; posterior – deep orbital cone; lateral – beginning of lateral orbital wall; medial – frontoethmoidal suture and nasolacrimal duct leading to retraction of the antero-medial wall. The implant has to be placed on remaining stable bony contours at the anterior and dorsal aspect of the orbital cavity (Fig. 41.7). The insertion of the implant itself is possible using a transconjunctival approach without canthoplastic extension.

For preoperative planning the virtual implant can be used to perform a reconstruction of the orbital floor and the medial orbital wall, which can simultaneously be used for intraoperative navigation without additional segmentation procedures. Additionally, this information determines the correct size of the implant.

A true-to-original reconstruction of the orbital walls, especially of the transition area between the

orbital floor and medial orbital wall are key procedures in orbital trauma management, and make a major contribution to the restoration of function and esthetics of the midface. Often the medial wall is simultaneously affected, which is one of the main reasons for postoperative problems of volume excess, dysfunction, and enophthalmus.^{1–6}

Compared to other methods, standardized orbital 3D implants have logistic and financial advantages, as no extra models have to be produced.^{28,30,34,79,80}

Therefore, virtual planning, implant fabrication, and surgical procedure are possible on the same day. This allows treatment on the same day, even in an emergency situation. However, trauma to the orbital roof or the skull base still cannot be considered.⁸¹ This can be a problem in malformations or defects where no remaining anatomical landmarks for correct placement exist. These virtual implants have their limitations, therefore, for preoperative planning.

Intraoperative imaging and postoperative control

CT with primary coronal sections (earlier) and multislice systems with secondary coronal reconstructions (nowadays) are accepted standards for preoperative diagnostic, planning, and postoperative control of midface fractures.²³ It has been repeatedly advocated that postoperative conventional radiography, cone-beam computed tomography (CBCT) or CT should be performed for control and self-correction for the surgeon.⁸² However, postoperative

Fig. 41.7 (a) 3D view of a left orbital cavity with the ideal position of a standardized preformed orbital implant. (1) Orbital rim, (2) inferior orbital fissure, (3) posterior orbital ledge, (4) transition between the medial wall and orbital floor (5) optic canal, (6) lacrimal fossa. (b) Coronal, (c) sagittal, and (d) axial view including a virtually placed implant for covering a fracture involving the medial orbital wall and large parts of the orbital floor.

controls outside the operation room are too late if instantaneous corrections are necessary and often a secondary reconstruction is not performed.⁸³

Intraoperative 2D fluoroscopy with a mobile C-arm system is well established in many surgical fields such as orthopedics and neurosurgery, but it is hardly used for craniomaxillofacial surgery, because projection fluoroscopy does not reveal the complex 3D structures of the filigree midface bones and cavities.^{84–86} The performance of intraoperative CT imaging for control of the surgical result of the head and neck region has already been described for orbito-zygomatic fractures.^{87,88} The advantage is in the possibility of getting intraoperative feedback for necessary surgical correction. However this technique involves enormous technical and financial expense and it must be kept in mind that during visualization of the midface region, sensitive structures like the lens are exposed to radiation.⁸⁹

The 3D rotational X-ray technique is well known from cardiovascular interventions.⁹⁰ New mobile C-arm systems such as Siremobil Iso-C^{3D} (Siemens AG, Medical Solutions, Erlangen, Germany) or Pulsera 3D-RX (Philips Medical Systems, Best, Netherland) permit intraoperative 3D imaging of bone structures.^{84,91} The C-arm images are comparable to CBCT images, and have shown no statistical difference in assessing the facial skeleton compared with CT.^{92,93}

The C-arm provides multiple images that are acquired about an isocentric point. The data provide tomographic images that may be reconstructed into 3D images like other 3D modalities. By panning the C-arm over the surgical field, no repositioning of the patient is necessary, and a fast intraoperative update

or postoperative control can be evaluated. By importing the C-arm dataset into the virtual planning dataset (diagnostic CT), automatic image fusion of both datasets leads to fast feedback about preoperative planning and the actual surgical situation (Fig. 41.8).

Conclusion

Orbital reconstruction still is a challenging surgical procedure. Preoperative planning and anatomic preformed implants are currently the technologies which define the highest standards in orbital reconstruction. Intraoperative data acquisition using cone-beam technology and the combination with the imaging fusion of the preoperative planning data are displacing navigation procedures and postoperative control CT scans.

Planning and sequencing of the treatment of panfacial fractures

Panfacial fractures are injuries of the facial skeleton involving the mandible, the midface, the naso-orbital-ethmoid area, and the frontal bone. The aim of the treatment in severe facial injuries is 3D reconstruction of the preinjury facial projections and restoration of form and function.

Diagnostics

CT scan with axial, coronal, sagittal, and 3D views is performed for diagnostics, often in the unconscious patient. The information of the CT scan concerning

Fig. 41.8 (a) C-arm data including the inserted implant after data acquisition during the operation procedure. (b) Coronal view and (c) 3D view of the image fusion, including the preoperative planning (red) done by mirroring the unaffected right side to the affected left side. Inserted implant presented in blue.

Fig. 41.9 (a) The axial view of a CT scan demonstrates a panfacial fracture with a comminuted bilateral centralateral midface. Loss of facial projection is noted by evaluation of the displaced fractures of the zygomatic arches. (b) Comminuted mandible fractures are seen. (c, d) Postoperative radiographs using coronal and lateral views demonstrate the result after open reduction and osteosynthesis. Note the miniplate osteosyntheses in the midface are located along the facial buttresses including the zygomatic arches. The mandible was reconstructed using a load-bearing reconstruction plate. Both orbital floors were repaired primarily using titanium mesh. (e) Following open reduction and osteosynthesis, 3D facial reconstruction was achieved.

the degree of dislocation and comminution of the fractures is important for sequencing of the treatment. Sequencing of the treatment is based on the clinical evaluation and the information of the CT scan concerning important areas such as the naso-orbital-ethmoidal (NOE) complex, the inner orbit, the zygomatic arches, the central midface with possible sagittal fractures, and the mandible with possible shortening of the ascending ramus due to fractures of the condylar process and lingual gapping of mandibular fractures, which can cause a widening of the lower face.

The diagnosis of intracranial injuries is important for primary management and for the planning and

timing of the treatment. Involvement of the frontal bone, the frontal sinus, and the skull base with intracranial injuries is common, and often an interdisciplinary treatment together with the neurosurgeon is indicated.

Radiographs are not indicated for the diagnosis of severe craniofacial trauma as no diagnostic information is added following a CT scan.

Airway

In severe panfacial injuries restoration of occlusion is important for reconstruction of the facial skeleton. When the occlusal unit needs to be reconstructed

Fig. 41.10 (a) The coronal view of a CT scan demonstrates a panfacial injury with severe midfacial fractures and bilateral deformation of the orbit. (b) The postoperative radiograph demonstrates the location of the miniplates. (c) Primary bone grafting using calvarian split grafts harvested by a coronal approach were used for the primary reconstruction of the left orbital floor. (d) A 3D reconstruction of a cone-beam CT scan demonstrates a stable result with 3D reconstruction of facial dimensions 8 years postoperatively. (e, f) Clinically, temporal hollowing can be seen, caused by an injury of the temporal muscle from an incorrect coronal approach at the time of immediate treatment of the cranial injuries.

endotracheal oral intubation should be avoided intraoperatively in dentate patients. Nasal intubation is often performed, however when nasal intubation is not indicated due to severe central midfacial and nasal injuries, the endotracheal tube can be placed via a submental incision. Tracheostomy is only recommended when long-term postoperative intubation is indicated due to concomittant injuries.

Approaches

Coronal, transconjunctival, and transoral approaches are performed. These surgical approaches are described in Chapter 40. In comminuted mandibular and condyle fractures, approaches such as submandibular, preauricular, retromandibular, or transoral endoscope-assisted approach, may be used depending on the preference of the surgeon (see Chapter 43). Bone injuries are treated prior to soft tissue injuries. Extended lacerations can be used for open reduction and fixation of facial fractures. All fracture sites need to be exposed before reduction and fixation are per-

formed. The coronal approach is performed when open reduction and fixation of fractures of the NOE complex, the frontal bone including the frontal sinus, and the zygomatic arches are indicated. When a coronal approach are performed, this facilitates harvesting of calvarian bone grafts.

Timing

Treatment should be performed during the first 7 days after trauma. Surgical treatment via a coronal approach is recommended for reconstruction of the outer frame of the face and restoration of facial projection by control of the frontal bar, the NOE complex, and zygomatic arches. A combined neurosurgical and craniomaxillofacial treatment is recommended when injuries of the frontal skull base and fractures of the posterior wall of the frontal sinus are present. Reduction of NOE, midfacial, and mandibular fractures may be performed first when surgery of the anterior skull base or for fractures of the posterior wall of the fontal sinus is indicated at a later stage,

Fig. 41.11 (a, b, c) Panfacial trauma with impression of the NOE complex and deformation of both orbits and involvement of the frontal sinus is demonstrated by 3D reconstruction, axial and coronal view of the preoperative CT scan. (d) The 3D reconstruction and coronal view 4 months postoperatively show restoration of the facial projections with narrowing of the intercanthal distance. (e) Following functional reconstruction of the frontal sinus and the nasofrontal duct, pneumatization of the paranasal sinus system is demonstrated. Normal sinus function is of importance to avoid long-term complications such as mucocele formation and sinusitis in the frontal region. (f) As the visual function was unclear in the unconscious patient, reconstruction of the inner orbit was not performed primarily. After recovery at 4 weeks postoperatively an inferior position of the left canthal ligament and bilateral enophthalmos with severe diplopia was noted. Following submandibular intubation an inconspicuous scar is located at the right submandibular region used for the primary repair of the panfacial injuries. (g) Secondary bilateral orbital reconstruction was performed using computer-assisted planning and intraoperative control of the placement of two individually preformed titanium mesh implants. The bilateral orbital reconstruction and the fixation of the right canthal ligament using a transnasal wire are demonstrated in a 3D reconstruction of a CT scan after corrective surgery. (h) Following bilateral orbital reconstruction and medial canthal ligament fixation, a satisfying esthetic and functional result was achieved, without enophthalmos or diplopia.

Fig. 41.12 (a) Panfacial trauma with severely dislocated midfacial fractures is demonstrated by 3D reconstruction of a CT scan. Due to intracranial injuries a neurosurgical treatment was not indicated at an early stage. To prevent difficulties of fracture reduction later than 2 weeks post-trauma, an open reduction of the periorbital, midfacial, and mandible fractures was performed without a coronal approach. (b) Extensive soft tissue swelling of the right zygomatic complex area did not allow anatomic reduction in this region. (c) During a second operation when a craniotomy for the treatment of the frontal skull base was performed, anatomic reduction of the right zygomatic complex was performed. Following the initial closed reduction of the NOE fractures, an anatomic reduction of the intercanthal distance was not achieved.

due to concomitant intracranial injuries, as precise fracture reduction after 14 days may be difficult. However, reduction of NOE fractures without a coronal approach may cause unsatisfying results. Sagittal fractures of the midface and the palate should be treated as early as possible, as reduction after several days may be difficult. In cases when early surgical treatment is not possible, transpalatal wires can be placed, even in the oral intubated patient, for closed reduction of sagittal palatal fractures to avoid widening of the midface.

Late reconstruction after 14 days leads to unsatisfactory results due to healing of fractures in malposition. Scarring with thickening of soft tissues and shrinkage of the overlying soft tissue envelope may cause unreparable deformities.

Therapy

Treatment strategies and sequencing of the treatment such as “top to bottom” or “bottom to top” have been described. A practical approach is to reconstruct the outer frame, with realignment of the zygomatic complex including the zygomatic arches and frontal bar, first. Reconstruction of the straight zygomatic arch is

important for restoration of the anterior–posterior facial projection.

In NOE fractures, reduction of the central fragment and exact repositioning of the medial aspect of the orbit with attachment of the medial canthal ligament is important, to avoid telecanthus deformity and broadening of the nose. Transnasal wiring can be used. A telecanthus deformity and broadening of the nose are difficult to correct secondarily and cause an unsatisfactory facial appearance. Reconstruction of the central midface and of the outer orbital frame is then performed. Widening of the face and enlargement of the orbit with enophthalmus deformity will result when the medial aspect of the orbit is not reduced adequately, as the infrarobital rim and the zygomatic complex will then be realigned based on the medial orbital fractures in malposition. Reconstruction of the paranasal and zygomatic buttresses is important for restoring the vertical height of the midface. Usually one or more buttresses can be reconstructed. A meticulous fracture reduction, even of small fragments, is recommended, especially in the buttress areas. Bone grafting may be indicated to achieve stable long-term results in areas with defects. Calvarian bone is the bone graft of choice. Mini- high and micro-osteosynthesis systems, such as 1.3 mini-plate systems, are recommended; they provide sufficient stability as mainly compressional forces are present in the midfacial area. The 1.3 plates are user friendly and allow for precise reduction and fixation without much bending of the plates, as the micro-plates adapt easily to the bone surface when the screws are tightened. In fractures with defects, stronger osteosynthesis systems such as 1.5 or 2.0 may be indicated.

An important factor for sequencing of the treatment is the occlusion present and the involvement of the mandible. In the dentate patient, restoration of the occlusion is important. In the edentulous patient, dentures may be helpful for reconstruction of facial height. Fractures of the anterior mandible frequently show lingual gapping which may cause widening of the face. Dislocated fractures of the mandibular condyle region and the ascending ramus often cause shortening of the ascending ramus which results in a unilateral or anterior open bite and incorrect vertical height of the face. When these fractures are present it is recommended to repair the mandible first before the occlusal unit is reconstructed. Correct mandibular reconstruction is not only important for restoration of the occlusal unit, but also to avoid broadening of the face. A broad face with an incorrect vertical height will result when the midface is realigned to a widened mandible with a shortened ascending ramus. For the reconstruction of comminuted mandible fractures a load-bearing osteosynthesis using rigid osteosynthesis plates such as 2.0 locking or reconstruction systems is indicated. An anterior rotation of the mandible with distraction of the condyles out of the temporal fossa should be avoided. When maxillomandibular

fixation (MMF) is applied, forward rotation of the mandible will cause a shortening of the midface and an anterior open bite when MMF is released. Anterior guiding elastics may be helpful to close an anterior open bite postoperatively. Arch bars should not, therefore, be removed at an early stage. For postoperative functional treatment using guiding elastics arch bars are better than MMF screws.

Reconstruction of the inner orbit is addressed last, following reconstruction of the outer frame, realignment of the NOE complex and the midface, and reconstruction of the mandible and of the occlusal unit. Repair of the walls of the inner orbit is of utmost importance for restoring ocular function and to avoid enophthalmos and diplopia. Furthermore the medial canthal ligament needs to be repaired when detached from the central fragment of the NOE complex to avoid telecanthus deformity. As the treatment of panfacial fractures is time consuming, orbital reconstruction by a second surgical team is recommended.

When the soft tissue envelope has been detached from the facial skeleton, resuspension of the midfacial soft tissue is mandatory to avoid soft tissue sagging, especially in the periorbital and midfacial region. Periosteal suspension sutures are used in the temporal and supraorbital areas.

Intraoperative imaging using cone-beam CT scan allows intraoperative control of the anatomic reduction of complex facial fractures, with reconstruction of the facial projections, to avoid secondary corrective surgery.

Summary

The challenge of panfacial fractures can be best met by careful preoperative planning and correct sequencing of treatment.

Chapter 42

Mandibular Trauma – Principles of Treatment

William Chung and Bernard J. Costello

Over the course of the past three decades, there has been a rapid development of techniques used in the management of mandibular trauma. Today's management of mandible fractures has allowed for decreased infection rates, increased rigid fixation over fracture segments with improved bony union, and a reduction in the use of wire maxillomandibular fixation, resulting in a faster return to function. The goal of this chapter is to present an overview of general treatment principles and outline advances in the management of mandibular fractures.

Historical background

Contemporary management of mandible fractures has allowed for a predictable outcome with decreased infection rates, increased rigid fixation over fracture segments with improved bony union, and a reduction in the use of wire maxillomandibular fixation, resulting in a faster return to function.¹ The diagnosis and treatment of mandibular fractures was documented as early as 1650BC in an Egyptian papyrus.^{2,3} Hippocrates described the use of external bandages to achieve fracture immobilization.⁴ Salicetti^{5,6} and Gilmer^{7,8} both reported the use of wires to perform maxillomandibular fixation in the treatment of mandibular fractures. Other early methods of fracture repair coincidentally resembled elements of more modern principles of rigid fixation and continued to revolve around Hippocrates' concept of immobilization.⁹

The management of mandibular fractures for the greater part of the 20th century was limited to the

application of maxillomandibular fixation, Gunning-type splints, or external frames used in combination with pin fixation.^{10,11} Fracture treatment by an open approach with direct transosseous wiring was eventually introduced, but was reserved for select cases involving the "edentulous" posterior mandible (i.e. ramus/angle) or in completely edentulous patients.¹² Luhr reintroduced the idea of using miniature bone plates in the repair of mandibular fractures in 1968 and 1972.¹³ In 1976, Speissl and others continued to advance the techniques of open reduction and internal fixation (ORIF) and developed the principles now advocated by the Arbeitsgemeinschaft für Osteosynthesefragen (Association for Osteosynthesis/ Association for the Study of Internal Fixation (AO/ ASIF)).¹⁴ In 1973, Michelet introduced techniques for mandibular fixation using smaller plates along ideal lines of osteosynthesis and Champy further refined and applied these techniques in clinical practice.^{15,16}

Etiology and epidemiology

The etiology of mandibular fractures includes assault, motor vehicle accidents, work- or sports-related injury, falls, projectile missiles, and pathologic fractures. The most common cause of mandibular fractures worldwide is motor vehicle crashes followed by assaults and occupational incidents.^{17–21} The circumstances and pattern of mandibular fractures are also quite variable depending on the population studied and the environment in which they live. More developed countries are likely to have a higher incidence of motor vehicle-related fractures, while underdeveloped nations typically report isolated fractures arising from altercations.^{17–21}

A number of studies that evaluated the location of mandibular fractures report the body as the most common site, at about 33%.^{18–21} Fig. 42.1 depicts the percentage of mandibular fractures based on anatomic location. The condyle and angle were also frequently reported at approximately 29% and 23%, respectively. Fractures occurred at the symphysis in nearly 9% of cases, while all other anatomic locations were infrequently involved. Depending on the mechanism of injury, fractures of the mandible comprise 10–25% of all facial fractures.²² Mandibular fractures are routinely reported as isolated from other facial fractures. Most studies that evaluated the number of mandibular fractures per patient reported a mean of 1.5–1.8 fractures.^{17–21} In numerous studies, more than 50% of all reported mandibular fractures occurred as multiple fractures.^{23–24} Frequent combinations of multiple mandibular fractures are angle and contralateral body, bilateral angle or body, and condylar and contralateral body.²⁵ Assaults typically resulted in left-sided fractures as most individuals are right-hand dominant.

Classification of mandibular fractures

Numerous classification schemes exist for mandibular fractures. These injuries have been classified based on the location of teeth relative to the fracture, anatomic region of the fracture, and fracture pattern. One particular classification scheme for angle and body fractures correlates the direction of the fracture line on a plain film with the role of the masticatory muscles on the fracture segments. This scheme describes the principle of *favorableness* in a horizontal and vertical plane. Figs 42.2–42.5 illustrate the principles of a favorable vs unfavorable fracture in both the horizontal and vertical plane. A fracture is favorable in a horizontal plane if the fracture resists the superior pull of the proximal fracture segment by the masseter and temporalis muscles. A fracture is favorable in the vertical plane if the fracture resists the medial pull of the proximal segment by the medial pterygoid muscle. Table 42.1 outlines classification schemes based on anatomic location and fracture pattern.

Table 42.1 Classification of mandibular fractures.

Anatomic region
Symphysis – fracture involving the area between the lateral incisors extending vertically through the inferior border of the mandible
Parasymphysis – fracture between the mental foramen and the mesial aspect of the canine extending through the inferior border of the mandible
Body – fracture between the mental foramen and the distal aspect of the second molar extending through the inferior border of the mandible
Angle – fracture between the distal aspect of the second molar and the posterior attachment of the masseter muscle extending through the inferior border of the mandible
Ramus – fracture extending horizontally through the anterior and posterior borders of the ramus or extending vertically from the sigmoid notch to the inferior border of the mandible distal to the second molar
Condylar process – fracture extending from the sigmoid notch to the posterior border of the ramus
Coronoid process – fracture involving the coronoid process
Alveolar – fracture confined to the tooth-bearing segment of bone
Fracture pattern
Greenstick – fracture through one cortex and no discontinuity of bone. No mobility of fractured segments. Common in children
Simple – fracture does not communicate with the external environment. A closed fracture
Compound – fracture communicates with the external environment either through the skin or the periodontal ligament of a tooth. An open fracture
Comminuted – multiple segments of bone as a result of greater force from the trauma
Complex – fracture involving damage to adjacent structures
Telescoped or impacted – one fractured segment is driven into the other segment
Pathologic – fracture resulting from normal function in an area of diseased bone
Terms associated with temporomandibular joint (TMJ) fractures
Displaced – movement of the condylar (proximal) segment relative to the remainder of the mandible. Although the condyle is malpositioned, it is still within the confines of the glenoid fossa and has not ruptured the capsule of the TMJ
Dislocated – the condylar (proximal) segment is no longer within the confines of the glenoid fossa
Extracapsular – fracture not involving the capsule of the TMJ
Intracapsular – fracture occurring within the TMJ capsule

Patient evaluation

The evaluation of mandibular fractures begins with obtaining a careful history. Information about the mechanism of injury often suggests a specific fracture pattern and may provide the surgeon with valuable insight regarding the potential for concomitant inju-

ries. In addition to focused questions about the traumatic event, the surgeon must carefully review the patient's past medical and surgical history, medication use, and any drug allergies. Pretrauma temporomandibular joint (TMJ) dysfunction and any associated non-surgical or surgical treatment should be carefully documented.

During the physical examination immediate attention must always be given to any problems associated with airway compromise or hemorrhage. Once the airway, breathing, and circulation have been adequately assessed, a neurologic evaluation should be performed. Standard trauma protocols such as those described in Advanced Trauma Life Support guidelines from the American Red Cross should be used during a comprehensive examination.²⁶ When a mandibular fracture is suspected, a thorough examination of the entire maxillofacial region is critical and should be carried out prior to ordering any radiographic studies.

A number of signs and symptoms are highly suggestive of a mandibular fracture (Table 42.2). Occlusal changes are one of the most common physical findings in patients with fractures of the mandible. Occlusal changes may be the result of dental fractures, fractures of the alveolus, trauma to associated structures of the TMJ, fractures of the maxilla, or contusions of the masticatory muscles. It is important to consider that the patient may have had a pre-existing malocclusion prior to the injury.

Deviation of the mandible on opening is indicative of a condylar fracture. In a unilateral condylar fracture, the mandible deviates to the side of the fracture due to the unopposed action of the lateral pterygoid muscle on the unaffected side and the lack of translation on the affected side. An open bite subsequently develops on the unaffected side and the posterior teeth contact first on the affected side. When bilateral condylar fractures occur the mandible does not necessarily deviate. However, the posterior occlusion does contact prematurely and an anterior open bite subsequently develops.

An altered range of motion can occur with mandibular fractures. The most common cause of limited opening is from pain and reflex guarding associated with the trauma. Decreased opening also occurs when a depressed zygomatic arch fracture mechanically impinges upon the coronoid process of the mandible. Muscle contusions and edema overlying any fracture site can also contribute to limited mouth opening.

A fracture should be considered when the force of a trauma is great enough to cause a laceration involving the perioral structures. Gingival lacerations may

be associated with either dental or alveolar fractures or they may indicate an underlying mandibular fracture. A more extensive degloving injury of the oral tissues may also be consistent with a fracture. A laceration to the chin should raise the surgeon's suspicion for not only a symphysis fracture, but also subcondylar fractures. Sublingual ecchymosis is also consistent for a mandibular fracture.

Lacerations of the lower lip or chin that involve a terminal branch of the mental nerve result in some degree of neurosensory deficit in this region. However, a neurosensory deficit along the distribution of the inferior alveolar nerve occurs when a displaced fracture traverses either the angle or body of the mandible. A non-displaced fracture typically does not manifest any neurosensory changes.

Changes in facial contour are often consistent with mandibular fractures. Bilateral angle or subcondylar fractures often displace the anterior mandible inferiorly, causing an elongated facial appearance. Bilateral parasymphyseal fractures often cause loss of chin projection. Any displaced fracture also creates loss of normal mandibular arch form.

A thorough otoscopic examination should be routinely performed during the evaluation of all maxillofacial trauma patients. However, the otoscopic examination plays a particularly important role for fractures of the condylar process. Dislocation fractures of the condyle can produce bleeding in the external auditory canal if the dislocated condyle tears the lining of the anterior wall of the canal. Basilar skull fractures may also be diagnosed when an otoscopic exam reveals blood behind the tympanic membrane.

Imaging

In clinical situations where the mechanisms of injury or physical examination are suggestive of a fracture, radiographic studies are necessary to confirm the diagnosis and plan subsequent treatment. An overview of radiographic methods in oral and maxillofacial surgery is given in Chapter 2. In the following paragraphs, specific considerations for mandibular fractures are presented.

When an isolated mandibular fracture is suspected, the routine radiographic assessment may consist of a panoramic radiograph and one additional postero-anterior view of the mandible, usually an open-mouth Towne's radiograph.²¹ A panoramic radiograph is the single most comprehensive image and usually allows for satisfactory visualization of all regions of the mandible (condyle, ramus, body, and symphysis) (Fig. 42.6). It is also useful for examining the existing dentition, and showing the presence of impacted teeth with respect to the fracture, the alveolar process, and the position of the mandibular canal.

The Towne's view adds another anatomic dimension and is especially useful in ruling out subcondylar

fractures. Fig. 42.7 clearly depicts a left subcondylar fracture, which is not as apparent in the panoramic radiograph of the same patient in Fig. 42.6. Some X-ray machines are capable of taking selective tomograms of the temporomandibular regions. Dedicated tomograms or transcranial views of the TMJ can be obtained as separate studies to further delineate the displacement of fractured segments. In situations where a panoramic view of the mandible is not available, a series of different views of the mandible is required to adequately view all of the anatomic regions of interest. This is more labor intensive, costly, and subjects the patient to a higher dose of radiation. Despite the good visualization of the dentoalveolar structures obtained by a panoramic radiograph, additional periapical or occlusal radiographs are often helpful in viewing specific areas of concern in more detail, especially when dental or alveolar fractures are suspected.

Currently computed tomography (CT) scans offer the most detailed and comprehensive view of the facial skeleton. Current protocols allow for axial, coronal, sagittal, and even reconstructed three-dimensional (3D) images to be formatted, as shown in Figs 42.8–42.11. Despite the superior visualization of the fracture(s), the use of CT scans for the diagnosis of isolated mandibular fractures is uncommon and may be cost-prohibitive. A CT scan is typically reserved for cases involving complex (comminuted, avulsive, etc.) mandibular injuries or concomitant midfacial or orbital injuries. In some cases where a dislocated condylar fracture is suspected, the CT scan will allow for detailed 3D imaging. Figs 42.12–42.14 depict both midfacial and mandibular fractures. Another useful application of the CT scan is in situations where the patient is not able to tolerate routine radiographic positioning and techniques (cervical spine or head injury). Very young patients with limited cooperation may also be candidates for CT scans, but may require sedation during imaging. When a CT scan is used, 2mm incremental axial and coronal views typically allow for sufficiently detailed imaging of the facial skeleton.

Fig. 42.7 Towne's radiograph of patient in Fig. 42.6.

Other studies can be helpful in specific scenarios, but are rarely required. Magnetic resonance imaging (MRI) is of very limited value in evaluating bony injuries. It may be helpful to delineate injuries to associated soft tissues or the intracapsular structures of the TMJ. Ultrasound has occasionally been used to determine condylar position after fractures. Angiography in conjunction with interventional radiology techniques can be used in situations where significant bleeding is associated with facial fractures.^{27–32}

Fig. 42.6 Panoramic radiograph of a patient who sustained a left subcondylar fracture.

Goals of mandibular fracture treatment

The goals of mandibular fracture repair are listed in Table 42.3. The primary goal is re-establishing a stable occlusion. This in turn allows for restoration of a normal mandibular arch form and facial symmetry. Once the occlusion and arch form are restored, emphasis is placed on resuming a normal range of motion, including excursive movements. Lastly, attempts are made to avoid long-term complications that may lead to internal derangement of the TMJ or growth disturbances of the condyle.

Treatment options

Closed reduction

Some patients may present with a mandibular fracture yet require no treatment. In these cases the occlusion is stable, the fracture is non-displaced, a favorable fracture pattern exists, and the patient is motivated to be compliant. Management in these rare instances consists of close observation, a liquid diet, and limited physical activity. The surgeon must remain prepared to change the treatment plan should any change in the clinical situation arise. If occlusal discrepancies or other signs of fracture displacement develop, then either closed or open reduction techniques should be implemented early.

Despite the technological advances in maxillofacial plating systems, most mandibular fractures are amenable to closed techniques.^{33–34} Those clinical scenarios well suited for closed reduction are listed in Table 42.4. Most non-displaced stable mandibular fractures lend themselves to closed treatment. Grossly comminuted mandibular fractures are at risk for devitalization and infection of the small bone fragments when open reduction techniques are performed due to the extensive periosteal stripping that is necessary to expose all of the fragments. This is especially relevant in fractures associated with gunshot wounds where additional hard and soft tissue necrosis is possible for several weeks following the initial injury.

A recent systematic review of open vs closed reduction of mandibular fractures showed that there are fewer complications when closed reduction is performed and the study raised doubts regarding the superiority of open reduction and rigid splinting compared to closed reduction and intermaxillary splinting.³⁵ Variables are difficult to control for in these studies, and the concept of what is a preferred outcome is debatable in the current literature. The balance between advantages and disadvantages of a closed vs open technique must be individualized as it should be with the use of all evidence-based decisions.

Atrophic edentulous mandible fractures present a unique challenge from a number of standpoints. These fractures typically occur in the elderly, so healing potential may be suboptimal. Because the blood

supply from the inferior alveolar artery is already compromised, limited osteogenic potential exists. The mandible now relies more heavily on the periosteum for its blood supply. Open techniques require stripping of the periosteum, further prohibiting osteogenesis.

Fractures involving a lack, or loss, of overlying soft tissue are best treated by closed techniques as the presence of hardware may increase the risk of infection. Adequate healing of any fracture is dependent on the blood supply to the area, which is partly contributed to by the quality and quantity of soft tissue coverage over the fracture. A soft tissue flap must be rotated over a fracture if an absolute loss of soft tissue has been determined.

The majority of mandibular fractures in children are best treated with closed techniques (discussed in more detail later in this chapter and elsewhere in this text). Developing tooth buds occupy a significant portion of the mandible and are at risk of injury with the placement of hardware commonly used in open techniques.³⁶ Pediatric patients can be placed into maxillomandibular fixation with circummandibular and piriform rim wires along with interpositional wires placed through the circummandibular wires. Figs 42.15–42.19 show circummandibular and piriform rim wires being placed followed by the maxillo-mandibular fixation wire. Fig. 42.20 shows the post-operative panoramic radiograph of the same patient. Pediatric fractures involving the mandibular arch may also be effectively managed using a lingual splint and circummandibular wires (Figs 42.21 and 42.22).

Most studies also support the treatment of condylar fractures in both children and adults with closed techniques.^{36–42} Regardless of the degree of radiographic displacement of the condylar segment, closed reduction and early postoperative physical therapy achieved excellent clinical results. These same studies also concluded that no correlation exists between radiographic alignment of the fracture and postoperative function.

Closed reduction of fractures is most commonly achieved by applying Erich arch bars to the maxillary and mandibular dentition with 24- or 25-gauge circumdental soft stainless steel wires (Fig. 42.23). The wires are tightened in a clockwise direction while

Fig. 42.15 Exposure of a piriform rim for placement of a skeletal fixation wire for a mandibular fracture in a pediatric patient.

Fig. 42.23 Erich arch bars and interdentally placed stainless steel 25-gauge wires.

Fig. 42.25 Intermaxillary fixation (IMF) bone screws and maxillomandibular fixation wires.

Fig. 42.24 Ivy loops made with 25-gauge stainless steel wires.

applying force in an apical direction. To avoid unnecessarily breaking the interdental wire, the wire is turned until it is lying flush against the arch bar. The end of the wire is then turned on to itself and crimped to prevent irritation or cutting of the gingiva or lip. It is advisable not to use Erich bars for splinting some simultaneously occurring dental injuries. For example repositioned and replanted and root-fractured incisors can be extruded by Erich bars, since the Erich bars are straight and have no occlusal curve built in. In these cases it may better to give the repositioned/replanted tooth a separate splint (see Chapter 39).

Wire loops are then wrapped around the hooks of the arch bars to maintain maxillomandibular fixation. Other closed reduction methods include Ivy loops (Fig. 42.24), Stout wiring, or Ernst and Gilmer ligatures. Some commercially available products have attempted to make the process of applying maxillomandibular fixation faster and easier. Bonded arch bar systems can be technically cumbersome if an absolutely dry field or healthy dentition are not present.

Another system for achieving maxillomandibular fixation involves the use of intermaxillary fixation (IMF) bone screws, which are modified to allow for passage of a wire ligature (Fig. 42.25). One of the potential complications of such a system is that the condyle can be distracted from the fossa in patients who do not have posterior dentition if the fixation

wires are overtightened. Edentulous and partially edentulous patients with severe fractures may benefit from the use of occlusal splints (Gunning-type) to maintain an interocclusal dimension and re-establish arch form. Significant comminution of the mandible with concomitant soft tissue loss may benefit from a period of external pin fixation. External fixators can be easily fabricated from an endotracheal tube and acrylic resin. The reaction is exothermic, so great care should be taken to avoid burning the patient's skin during the bar's fabrication.

Open reduction

Several clinical scenarios support the use of open reduction in the repair of mandibular fractures (Table 42.5). Patients with certain systemic conditions may be more appropriately treated with an open technique. Patients with a severe seizure disorder are unlikely to tolerate maxillomandibular fixation. Patients with other neurologic or psychiatric conditions may also benefit from open techniques as would patients with either decreased pulmonary function or gastrointestinal disorders.

A displaced and unfavorable fracture of the mandible cannot be adequately treated with maxillomandibular fixation alone. The influence of the masticatory muscles on angle fractures or the digastric and suprahyoid muscles on parasymphysal or body fractures causes undesirable rotation of the proximal segments and opening at the inferior border. These changes prevent the lingual cusps of the posterior teeth from

Table 42.5 Indications for open reduction techniques of mandibular fractures.

Systemic disorders
Displaced unfavorable fractures
Multiple facial and/or mandibular fractures
Bilateral condylar fractures and midface fractures
Delayed treatment with soft tissue in between the fracture
Malunion/non-union

occluding and may result in masticatory insufficiency and periodontal changes.⁴³

If a patient sustains multiple fractures of the facial bones and/or the mandible, open reduction of the mandibular fractures allows for a more stable foundation for further reconstruction, especially if other facial bones are involved. When bilateral condylar fractures occur in conjunction with midfacial fractures, at least one of the condylar fractures must be opened and fixated to re-establish the vertical dimension of the face. Further discussion of open techniques for condylar fractures occurs later in this chapter.

Most condylar fractures are best treated with closed reduction for approximately 2 weeks. Then the mandible is actively mobilized to avoid an altered range of motion. When a condylar fracture occurs concurrently with another mandibular fracture, it is favorable to open the non-condylar fracture to allow for the necessary postoperative mobilization of the mandible after the 2-week period of maxillomandibular fixation.

When circumstances such as a closed head injury or other acute illnesses prevent the timely repair of a mandibular fracture, soft tissue may grow in between the fracture segments. The soft tissue within the fracture must be removed and an open approach used to repair the fracture. If a malunion or non-union results from the repair of a mandibular fracture, an open approach is necessary to correct the problem.

With the advent of miniplates and bone screws, it has become widely accepted that most fractures involving the craniomaxillofacial skeleton are now treated with open reduction and internal fixation techniques. An open approach gives the surgeon optimal visualization of the fracture segments, therefore allowing the best possible anatomic reduction. Fractures involving the mandibular symphysis, parasymphysis, body, and occasionally the angle may be successfully approached through a transoral approach. The rich blood supply of the maxillofacial skeleton allows for wide subperiosteal dissection and exposure of the mandible without compromising the vascularity and subsequent healing of the bony segments. A transoral approach begins with a vestibular incision at least 1 cm from the mucogingival junction to avoid damage to the attached periodontal tissues and to allow for greater ease of closure of the incision. In the anterior mandible, the mentalis muscles are initially divided during the dissection. During closure, these paired muscles must be reapproximated using interrupted sutures as a separate layer to avoid either a dehiscence of the hardware or the "witch's chin" deformity. Care should be taken to avoid the mental nerves as they exit the mental foramen near the bicuspid roots. Fig. 42.26 depicts a skeletonized mental nerve carefully positioned over the fixation hardware placed through a transoral incision. Full exposure of the buccal surface of the inferior border is required to place adequate fixation. Fractures of the mandibular angle or ramus can be approached through a poste-

Fig. 42.26 Skeletonized mental nerve positioned over the tension band and fracture plate.

rior vestibular incision. This incision starts just below the external oblique ridge and courses anteriorly approximately 5–7 mm below and parallel to the mucogingival junction. A full-thickness mucoperiosteal flap is elevated. However, a transoral approach may still not allow for direct placement of screws across the fracture site. In such instances the use of a percutaneous trocar may become necessary to allow for the perpendicular placement of the bone screws.

There are also several techniques used to approach the mandible using an extraoral incision, which are reviewed in the Surgical approaches section of this chapter. While it is possible to approach the entire mandible from an external approach, approaches that require skin incisions are usually reserved for fractures involving the posterior body, angle, ramus, or subcondylar regions. Indications for the use of an extraoral approach include the presence of pre-existing lacerations over the fracture, complex fractures, or an edentulous mandible fracture. In edentulous or partially edentulous patients, a vestibular incision may cause scarring and obliteration of vestibular depth, complicating subsequent prosthetic use. Fractures in the anterior region can be approached through a submental incision, but most are dealt with more effectively through an intraoral approach without the need for external scarring.

Surgical approaches

Several factors are considered in the selection of an incision: the degree of exposure required; fracture location; and existing skin crease(s). First described by Risdon⁴⁴ in 1934, a submandibular approach can be used for fractures involving the mandibular angle, ramus, or subcondylar region (Fig. 42.27). The incision is approximately 4 cm long and is placed 1.5–2 cm below the angle and inferior border of the mandible. Placing the incision in an existing skin crease allows the scar to be hidden. The skin and subcutaneous fat are incised until the platysma muscle layer is identified. Once the platysma muscle layer is reached, a nerve stimulator is used to help identify the marginal

Fig. 42.27 Two locations for a submandibular incision. Incision **A** parallels the inferior border of the mandible. Incision **B** lies within a resting skin tension line. **B** may leave a less conspicuous scar in patients. (Figure 9.3, p. 156 from Ellis E, Zide MF. *Surgical Approaches to the Facial Skeleton*, 2nd edn. Philadelphia, PA: Lippincott Williams & Wilkins, 2006. Reproduced with permission. Copyright © 2006 Lippincott Williams & Wilkins.)

mandibular branch(es) during the remainder of the dissection. The marginal mandibular nerve is located just deep to the superficial layer of the deep cervical fascia. The dissection continues to follow a plane superficial to the capsule of the submandibular gland, proceeding superiorly towards the inferior border of the mandible. The marginal mandibular nerve usually has two branches and typically passes above the inferior border of the mandible proximal to where the facial artery crosses the mandible. If necessary the facial artery and vein can be divided and ligated. Lastly, the pterygomasseteric sling and periosteum are incised to access the fracture segments.

The retromandibular incision also accesses fractures of the mandibular ramus or subcondylar region, as shown in Fig. 42.28. Initially described by Hinds and Girotti,⁴⁵ this incision is similar to the submandibular incision, but it curves upward and behind the angle of the mandible. This approach involves the parotid and masseteric fascia in the course of the dissection. When incising through the masseter muscle, the marginal mandibular and buccal branches must be identified and protected. The primary advantage of the retromandibular incision over the submandibular incision is its greater exposure of the ramus and subcondylar regions.

The preauricular incision is a modification of an incision initially designed by Blair.⁴⁶ The incision provides maximal lateral and anterior access to the joint space. The incision is approximately 3 cm long and has a superior and inferior component, which meet at a point level with the superior aspect of the tragus (Fig. 42.29). The incision is placed within a preauricular skin crease that lies posterior to the superfi-

Fig. 42.29 Preauricular incision. (Figure 12.7, p. 199 from Ellis E, Zide MF. *Surgical Approaches to the Facial Skeleton*, 2nd edn. Philadelphia, PA: Lippincott Williams & Wilkins, 2006. Reproduced with permission. Copyright © 2006 Lippincott Williams & Wilkins.)

cial temporal vessels and the auriculotemporal nerve. The vessels can be avoided by following the preauricular cartilage during the dissection. Sufficient surgical access in the inferior portion of the incision can be easily achieved by carrying the incision to a point just below the tragus, but the incision can be extended inferiorly to the level of the lobule.

After sharply incising the skin and subcuticular tissues the superior portion of the incision is progressively dissected with mosquito hemostats to the intensely white temporalis fascia. The inferior por-

tion of the incision is dissected down to the lateral TMJ ligament. Because the external auditory canal is angled nearly 45° anteromedially to the skin surface, the inferior portion of the dissection follows the pretragal pocket to avoid perforating into the external auditory canal. A curved Metzenbaum scissors is placed in the superior aspect of the incision on top of the temporalis fascia and directed inferiorly toward the TMJ ligament. The overlying tissues are sharply incised and a flap is reflected anteriorly and superiorly exposing the temporalis fascia. The flap is also retracted anteriorly away from the tragus. A scalpel is used to make a vertical incision through the temporalis fascia and the dissection proceeds down to the zygomatic arch. Then a full-thickness flap is elevated anteriorly off the arch until the articular eminence is visualized. The lateral TMJ capsule is identified and incised off the lateral lip of the zygomatic arch. Fig. 42.30 depicts the lateral capsular attachment excised off the arch to expose the superior joint space.

Basic principles of internal fixation

The basic principles of mandibular fracture repair using internal fixation can be summarized as reduction, stabilization, and fixation. Open reduction and application of rigid internal fixation is ideally carried out under general anesthesia with a contoured nasal endotracheal (RAE) tube. If a nasal tube cannot be used because of a concomitant midfacial injury preventing safe passage of a nasal tube, then a tracheostomy may have to be considered. If an edentulous space exists in the dentition, then an oral endotracheal tube can be placed in this space.

After an airway is established, arch bars are secured to the maxillary and mandibular dentition using 24 or 25 gauge stainless steel circumdental wires. When possible, a stable and reproducible occlusion is verified. Then the patient is secured into the stable occlusion with ligature wires wrapped around the

hooks of the arch bars. Next, if an extraoral incision is planned, it is demarcated with a sterile surgical marking pen and the soft tissues are injected with a local anesthetic solution containing a vasoconstrictor. Exposure of all fractures is completed using a broad periosteal elevator to allow direct visualization of the fracture segments. When multiple fractures are present, the longest, most stable segments are rigidly fixated first.

Once the bone plates and screws have been placed, the wound is packed and the wire maxillomandibular fixation is removed. Removal of the wires allows for evaluation of not only the restored mandibular arch form but also of the occlusion by moving the mandible. Releasing the maxillomandibular fixation also facilitates closure of extraoral incisions by relaxing the soft tissues in the neck. If a malocclusion develops during the early postoperative period, then training elastics can be placed on the arch bars to assist in the re-establishment of a proper occlusion. The use of elastics limits the degree of mandibular movement, but allows for better oral intake, hygiene, and is often better tolerated by patients. The elastics are also beneficial for neuromuscular training while the patient attempts to return to a normal range of motion. The arch bars and interdental ligature wires are usually removed 4–6 weeks postoperatively. If an ideal anatomic reduction and stable occlusion are achieved intraoperatively, the arch bars and interdental ligature wires may be removed at the end of the surgical procedure.

The primary advantage of rigid internal fixation is that it usually obviates the need for postoperative maxillomandibular fixation and allows for a faster return to function. The application of low-profile titanium alloy plates with self-tapping screws requires less soft tissue stripping than was required in procedures for open reduction with the direct application of transosseous wires. Other advantages of rigid internal fixation include better anatomic reduction, greater stability across the fractured segments, improved healing, and decreased mobility, which further reduce the incidence of infection.

While the details of rigid and semi-rigid fixation are well beyond the scope of this chapter, some basic concepts merit discussion. The introduction of fixation plates and screws has revolutionized the treatment of mandibular fractures. Systems currently used for rigid internal fixation of mandibular fractures include plates and screws of a variety of sizes and configurations. Tension band plates or Champy-style plates generally use 2.0mm screws, while inferior border plates use 2.3–2.7mm screws. At least two screws on either side of a fracture are required for 3D stability, and care is taken to avoid placing screws into the mandibular canal. Plates placed at the inferior border (compression zone) are generally placed through both the outer and inner cortices of the mandible, while superior border (tension band) plates are placed through only the outer cortex.

Fig. 42.30 Exposure of the superior joint space via a preauricular incision. Note the superior surface of the TMJ meniscus.

The use of a locking plate and screw has also been advocated in the repair of mandibular fractures. The locking screw has a second set of threads under the head of the screw that engages reciprocal threads on the inner aspect of the hole within the plate. One technical advantage of this design is that the plate does not have to be perfectly adapted against the lateral aspect of the mandible because the screw head “locks” into the hole of the plate. Thus, the locking plate and screw does not require the fracture segments to be compressed against the plate.

More recently, bone plating systems made from resorbable polymers have been used in clinical practice. Early resorbable plating systems were thick and reported to experience cracking under stress, possibly preventing osteosynthesis at the fracture site.⁴⁷ As the systems became more refined, the hardware became thinner and could be placed through transoral incisions. Kim *et al.* studied the use of resorbable plates for mandibular fractures and reported consolidation in all of the patients and an 8% complication rate.⁴⁸ Despite encouraging clinical reports and growing enthusiasm among surgeons, a careful clinical outcome measure analysis on the use of resorbable plating systems must be completed before widespread use is advocated for mandibular fractures. The resorbable materials themselves and the techniques used in their application continue to be redefined.^{49, 50} The topic of resorbable plating systems in the treatment of craniofacial and mandibular fractures is also discussed in Chapters 40 and 41.

The fundamental techniques of rigid fixation include: placement of a tension band, where necessary; passive adaptation of the plate to the properly reduced fracture segments; appropriate positioning of screws in relation to adjacent anatomic structures; placement of screws in accordance with the principles of dynamic compression, where appropriate; and the use of plates and screws of adequate strength and durability. Some surgeons advocate the use of larger screws (2.3 or 2.7 mm) with a fracture plate versus two smaller miniplates. The belief is that the larger fracture plate is necessary to adequately stabilize the segments and neutralize all forces that may occur during function.⁵¹

In 1999, Potter and Ellis examined 46 patients with 51 fractures involving the mandibular angle that were treated using a malleable non-compression plate placed at the superior border of the mandible.⁵² All of the patients had uncomplicated healing of the fractures, suggesting that the required level of fixation for this type of injury is less than previously thought. The advantages of treating fractures with smaller bone plates include less dissection and morbidity. Some of the data showed a decreased incidence of infection in patients who underwent limited dissection and had a less rigid plate placed.⁵³ Insufficient prospective data currently exists to determine which technique is best suited for each fracture of the mandible.

An alternative technique for fixation of mandibular fractures is the lag screw technique. This technique compresses the fracture segments by placing screws through two intact and stable cortices. The hole in the outer cortex is the same diameter as the outer diameter of the screw threads and is also countersunk to receive the head of the screw. This hole is referred to as the gliding hole. The hole in the inner cortex is the same diameter as the internal diameter of the screw. Thus, proper placement of a lag screw requires drilling the hole in the outer cortex slightly larger than the diameter of the inner cortex. When the screw is tightened, the segments are compressed because the head of the screw compresses the outer cortex against the inner cortex while the threads of the screw engage the inner hole (Figs 42.31 and 42.32). A lag screw is placed at a 90° angle to the fracture line to prevent displacement of the fracture segments. Placement of a second lag screw is required to resist rotational forces around the long axis of the first screw.

The lag screw technique offers several advantages over bone plates. First, less hardware is involved. Second, this technique requires less time. Third, the anatomic reduction of the fracture is often better with lag screws than with bone plates. However, the lag screw technique should not be used in either comminuted fractures or fractures involving loss of bone. Lag screw fixation involving the ramus or subcondy-

Fig. 42.31 Axial CT scan of a symphysis fracture that will be reduced and fixated with the lag screw technique.

Fig. 42.32 Placement of a lag screw through the symphysis fracture.

lar region is more technically demanding. Often, a trocar may be necessary to place the lag screw in the posterior mandible without damaging adjacent structures.

Complications of mandibular fracture repair

Complications following mandibular fracture repair are uncommon; infection is the most common. Complications create unique challenges for even the most experienced surgeon and may result in cosmetic and/or functional disturbances. Complication rates have improved since the use of wire fixation, but even the most sound fixation techniques can yield undesirable results.

Infection

Infection is the most common complication of surgical intervention. Lister introduced the concept of asepsis prior to and during an operation.⁵⁴ His concept of decreasing microbial numbers to allow the host to overcome the virulence of the bacteria dramatically reduced infection rates. The potential for infection is always a consideration when treating mandibular fractures, especially when fractures communicate with the oral cavity, as in compound fractures.

Numerous reports have reported various postoperative infection rates associated with mandibular fracture repair, varying from less than 1% to 32%.⁵⁵⁻⁵⁹ A prospective randomized study was performed by Zallen and Curry evaluating the role of antibiotics on dentate patients who sustained compound mandible fractures.⁶⁰ The study revealed an infection rate of 50% at the fracture site for patients who did not receive antibiotic therapy compared to an infection rate of only 6% of those who received antibiotics. The rate of infection did not appear to be related to either an open or closed technique. Abubaker *et al.* performed a prospective, randomized, double-blinded study evaluating the role of postoperative oral antibiotics in uncomplicated mandibular fractures.⁶¹ The study reported no advantage in treating uncomplicated fractures with antibiotics.

One of the many risk factors associated with infection following repair of a mandibular fracture is active substance abuse or patient non-compliance with postoperative regimens.⁶² A significant delay in treatment has also been associated with an increased rate of infection.⁶³ A treatment time between 3 and 5 days after trauma has been shown to be optimal with the lowest rate of infection, in a recent literature review.⁶⁴ Other risk factors include gross contamination of the fracture, pre-existing dentoalveolar disease, teeth within the line of fracture, poor host healing potential, and severe bone resorption patterns associated with edentulous mandibles.

Most infections of the oral cavity are polymicrobial. Both anaerobes and aerobes have been routinely cultured from infections related to mandibular fracture repair. The most common organisms cultured are *Staphylococcus*, α -hemolytic *Streptococcus*, and *Bacteriodes*. Manifestations of an infection include abscess formation, cellulitis, formation of a cutaneous fistula, osteomyelitis, and, rarely, necrotizing fasciitis. Figs 42.33 and 42.34 depict a cutaneous fistula from infected hardware placed for a fracture. Early in the course of the infection, the bacterial population is largely aerobic and Gram positive. As the infection progresses and becomes more chronic, the composition of the involved organisms changes so that anaerobic, Gram-negative organisms predominate. For more detailed information regarding infection in oral maxillofacial surgery see Chapter 29.

Management of these infections begins with a detailed clinical examination followed by appropriate imaging to assess the status of the fractured segments and the hardware. Appropriate laboratory studies, including a complete blood count, should be obtained when clinical indications are present. The use of CT scans or an MRI is appropriate when there is concern that the infection involves the surrounding soft tissues of the neck. Specimens for bacterial culture and sensitivity studies should be sent as early as possible in the patient's clinical course.

Penicillin G, with its excellent Gram-positive coverage, is appropriate for early infections, while clindamycin, with its broader Gram-negative coverage, may become necessary for chronic infections. Antibiotic therapy should begin preoperatively, but the specific length of postoperative antibiotic therapy varies with each circumstance.

It is well documented that the elimination of some of the causative organisms will successfully change the complex microenvironment enough to resolve infections in and around the oral cavity.⁶⁵ Use of broad-spectrum antibiotics in the initial management of an infected fracture is usually reserved for severe infections or when the host's immune responses are

Fig. 42.33 Cutaneous fistula in a patient who had hardware placed for a symphysis fracture.

Fig. 42.34 Panoramic radiograph of patient in Fig. 42.33. Note the radiolucency associated with the innermost right fixation screw.

compromised. When initial empiric antibiotic therapy fails to resolve the infection, bacterial culture and sensitivity studies help redirect the surgeon's selection of antibiotics.

Successful resolution of most surgical infections requires three steps: (1) the development of adequate drainage; (2) removal of the source; and (3) appropriate antibiotic coverage. If the infection is the result of a non-restorable tooth or sequestrum, removal of the etiologic agent is required. When fluctuance is present, incision and drainage are necessary to establish prompt resolution. Patients with an infected non-union fracture require debridement and definitive stabilization using one of several methods previously described.

The type of fracture immobilization has been shown to be a factor in the incidence of complications associated with mandibular fractures. Passeri and colleagues reported a 14% rate of infection in mandibular fractures treated with closed reduction.⁶² Infections treated with closed reduction are often associated with either carious or periodontally compromised teeth or teeth within the line of fracture. Luhr examined mandibular fractures treated with closed reduction, dynamic compression plating, and wire fixation.⁶⁶ He found a similar incidence of infection associated with closed reduction and open reduction using dynamic compression plating, but an increased incidence of infection when wire fixation was used. This finding was thought to be due to the mobility of the segments associated with wire fixation. Ellis and colleagues have evaluated multiple types of fixation methods for mandibular fractures.^{53,58,67,68} Ellis observed the highest rates of infection in patients who received two dynamic compression plates. Wire fixation was associated with an infection rate approaching 25%. Champy originally reported an infection rate of only 3.8% associated with his technique of using a 2.0 mm tension band plate via a transoral approach.¹⁶ These data suggest that the use of larger plates may not necessarily be the best treatment for all fracture scenarios. Prospective outcome trials comparing different techniques for similar fracture patterns are needed to properly evaluate these techniques.

Malunion

A malunion is defined as a fracture that has formed a bony union but is misaligned. A malunion usually becomes clinically relevant when it results in a malocclusion. A significant malunion can also result in facial asymmetry and can only be corrected through a carefully planned osteotomy. Malunions are initially treated with conservative therapies such as occlusal equilibration, extended maxillomandibular fixation, or orthodontic mechanics. When the degree of displacement of the segments has significantly altered the occlusion, orthognathic surgery may be necessary to restore normal form and function.

A thorough understanding of dental anatomy and masticatory dynamics is essential in the comprehensive treatment of mandibular fractures to avoid creating a postoperative mandibular arch deformity. Preoperative study models and splint fabrication may aid in fracture reduction in complex cases. Failure to re-establish an anatomic arch form may result in a malocclusion, functional disorders, and facial asymmetry.

Non-union

A non-union exists when bone healing does not occur at a fracture site. A patient experiences pain and clinical mobility over the fracture site in a non-union. A malocclusion is also likely if the non-union occurs in the tooth-bearing portion of the mandible. A radiograph of a non-union often reveals a persistent non-healed fracture with rounded edges adjacent to the fracture segments. The most common cause of a non-union is inadequate reduction and immobilization of the fracture.⁶⁹ In his study of 577 patients, Mathog reported an incidence of non-union fractures of 2.4%.⁷⁰ Other contributing factors of a non-union are infection, severity of the fracture(s),⁷¹ poor blood supply to the mandible, the presence of teeth in the line of fracture,⁷²⁻⁷⁵ metabolic disorders and poor nutritional status,⁷⁶ and patient non-compliance.⁷⁷ Regardless of the surgical technique used, the incidence of a non-union was no greater than 4% in multiple studies.⁷⁸

Treating a non-union begins with identifying and removing the cause of the non-union. If a fracture was inadequately reduced and immobilized, the existing hardware must be removed then properly replaced. All sources of infection must be completely identified. Once the necessary steps have been taken to remove these sources (failed hardware, sequestrum, fistulous tracts, etc.) then appropriate fixation techniques may be used to refixate the fracture. Bone grafting procedures may become necessary when a continuity defect results from the removal of non-viable bone along the edges of the fracture segments.

Nerve injury

The inferior alveolar nerve is the most commonly injured nerve resulting from a mandibular fracture.⁷⁹ Fractures that involve the mandibular body or angle will frequently result in some degree of neurosensory disturbance depending on the degree of fracture displacement. Other branches of the mandibular nerve (auriculotemporal, masseteric, buccal) are at risk of injury usually from a laceration rather than an isolated fracture. The presence of any sensory disturbance following a mandibular fracture should be documented both pre- and postoperatively. A detailed objective neurosensory examination should be performed when the patient reports no improvement in the level of sensation after 6–8 weeks. Most sensory dysfunction improves with time unless the initial injury resulted in a severely displaced fracture and gross disruption of the nerve.

Few studies have focused on sensory deficits associated with mandibular fractures. One particular study by Moore and colleagues reported an incidence of paresthesia of the mental nerve of less than 2%.⁸⁰ They also reported a rate of facial nerve injury of 1.8%. Permanent sensory dysfunction of the mental nerve following mandibular fractures was reported by Larsen and Nielsen.⁸¹ Branches of the facial nerve are also at risk of injury as a result of mandibular fractures. Several studies reported paralysis of the facial musculature following condylar fractures.^{82–84}

Temporomandibular joint dysfunction and ankylosis

Condylar fractures can result in internal derangement of the TMJ. De Riu *et al.*⁴⁰ reported a higher incidence of TMJ pain, joint noises, and deviation on opening in patients who sustained fractures of the condyle. Internal derangement can develop both on the side of the fracture and in the contralateral TMJ. Certain condylar fractures may create a unilateral hinge motion on the affected side. This scenario has resulted in overfunction in the contralateral joint and subsequent hyperactivity and disc dislocation.⁸⁵ Chuong and Piper described using an open technique with direct repair of the altered soft tissues to avoid internal

derangement, but no long-term data exist to support their technique.⁸⁶

Ankylosis is a rare complication of condylar fractures and usually occurs with either an intracapsular fracture in children or prolonged immobilization for the treatment of a mandibular fracture. Ankylosis is thought to develop from intracapsular hemorrhage with subsequent pathologic fibrosis.⁶⁹ If the ankylosis is untreated, it results in underdevelopment of the mandible on the fractured side. Ankylosis can be treated by a gap arthroplasty and any number of adjunctive procedures such as a coronoidectomy and replacement of the condyle with a costochondral rib graft in children or a prosthetic joint in adults. Shorter periods of maxillomandibular fixation, aggressive postoperative physiotherapy, and compliance with follow-up visits are all essential in avoiding ankylosis of the TMJ.

Growth disturbances

Condylar fractures may result in growth disturbances of the mandible. It was previously thought that the cartilage associated with the condyle served as a growth center. However, Durkin *et al.*⁸⁷ believe that the condylar cartilage behaves as a remodeling center after a traumatic injury. They describe a process where the condyle can resorb and a new condylar apparatus subsequently develops. However, this new condyle can grow to larger proportions, especially if the joint space on the affected side is not appropriately maintained and the occlusion is not properly re-established.

Complete condylar regeneration can occur in children, especially in children less than 12 years of age and in those who are still actively growing.^{38,88} This finding was supported by studies that surgically induced fracture dislocations of the condyle in monkeys.⁸⁹ No growth disturbances were noted in any of these monkeys. Thus, the ability of young children to resume normal growth of the mandible contradicts the previously held belief that condylar fractures produced a much greater risk of growth disturbances in younger children.⁹⁰

Facial widening

Widening or flaring at the mandibular angles often occurs after a mandibular symphysis fracture, bilateral condyle fractures, or both. The action of the tongue and suprahyoid musculature causes flaring and lingual tipping of the buccal segments. The fracture line on the outer cortex at the symphysis appears non-displaced. However, direct visualization of the inner cortex reveals separation at the fracture. Ellis describes putting pressure in an inward or medial direction at the gonial angles during the reduction of the fracture(s) while placing the fixation, to avoid this complication.⁹¹

Special considerations

Teeth in the line of fracture

In years past any tooth adjacent to a fracture line was removed because the tooth was considered a direct communication between the fracture and the oral cavity by way of the periodontal ligament. However, several studies concluded that not all teeth required removal when antibiotic therapy and rigid fixation were appropriately implemented.^{74,92,93} Shetty and Freymiller discussed the clinical indications for removal of teeth in the line of fracture (Table 42.6).⁹⁴ These indications hold particularly true for an impacted mandibular third molar associated with an angle fracture. When the third molar does not prevent the fracture from being reduced or is not in direct communication with the oral cavity, the tooth does not need to be removed.

Condylar fractures

The treatment of condylar fractures remains a highly controversial topic in oral and maxillofacial surgery. Each case must be individually evaluated before a particular treatment plan is initiated. Early classification systems of condylar fractures, such as those by Lindahl⁹⁵ and Thoma,⁹⁶ were based on anatomic location of the fracture and the relationship of the condyle to the remaining mandible and the glenoid fossa. Although comprehensive, these particular classification systems did not assist in directing treatment option(s) or affecting the clinical outcome.

MacLennan⁹⁷ developed a classification system that described the degree of fracture displacement, making his scheme more useful in selecting a surgical treatment plan. A type I fracture is non-displaced, whereas a type II fracture involves deviation of the proximal or condylar segment with a simple angulation but no overlap or separation of the fracture segments. In a type III fracture, the condyle is displaced and the fracture segments are overlapped. Lastly, type IV fractures are fracture dislocations where the condyle is completely dislocated out of the confines of the fossa and capsule.

Table 42.6 Indications for removal of teeth in the line of fracture.

Grossly mobile teeth with periapical pathology or significant periodontal disease
Partially erupted third molars with pericoronitis or an associated cyst
Teeth that prevent adequate reduction of the fracture
Teeth with fractured roots
Teeth with exposed root surface from the apex to gingival margin
Excessive delay from the time of fracture to definitive treatment

The goals of condylar fracture treatment include the re-establishment of form and function, which include restoring the occlusion, range of motion, and facial symmetry. Table 42.7 lists both early and late complications from either untreated, or improperly treated, condylar fractures. Currently insufficient clinical data exist to support the use of open reduction for condylar fractures in children or adults. Most condylar fractures are best treated with closed reduction. Contemporary management of condylar fractures now includes endoscopic techniques, which are discussed in greater detail elsewhere in this textbook.

Several absolute indications exist to support the use of open reduction techniques for certain condylar fractures (Table 42.8). Open reduction is performed in situations where closed reduction is not possible or mandibular dysfunction is likely to result if an open reduction is not performed. Mandibular dysfunction may be associated with the following: a fracture dislocation that creates a mechanical stop; displacement of the condyle into the middle cranial fossa; a foreign body in the joint space; or a lateral extracapsular dislocation of the condyle.

Relative indications also exist to support the use of open techniques when treating condylar fractures, as listed in Table 42.9. Certain systemic conditions favor the use of an open technique, such as poorly controlled seizures, severe mental retardation, or psychiatric disorders. Patients with closed head injuries may not tolerate maxillomandibular fixation unless a concurrent tracheostomy is planned. If a tracheostomy

Foreign body in the joint space
Lateral extracapsular dislocation of the condyle

my is not desired, then an open reduction may be indicated.

Patients who sustain bilateral condylar fractures and concomitant comminuted midface fractures require re-establishment of the vertical dimension of their midface. An open reduction of at least one of the condylar fractures allows the the midfacial height to be restored, especially if the comminuted midface fractures cannot be rigidly fixated. An open reduction is also favorable when bilateral condylar fractures prevent a stable and reproducible occlusion from being achieved. Another scenario amenable to open reduction is in the presence of a displaced condylar fracture and an inability to perform maxillomandibular fixation due to a lack of pre-existing dentures or severe alveolar bone resorption preventing the fabrication of a lingual splint.

Reports by both Ellis and Dean⁹⁸ and Mikkonen *et al.*⁹⁹ describe using an extraoral vertical ramus osteotomy with removal of the posterior ramus for access to severe medial dislocations of high condylar fractures. This technique allows for improved visualization of and access to the proximal segment for adequate reduction. Figs 42.35–42.38 show a CT scan of a patient with bilateral dislocation fractures of the condyles and a concurrent symphysis fracture. The only major concern with this technique is the theoretical risk of avascular necrosis of the condylar head. However, both studies reported minimal dysfunction and no radiographic evidence of irreversible changes of the condyle.

A technical point of interest involves “preplating” the posterior ramus at the osteotomy site. A reciprocating saw is used to demarcate the desired location of the vertical osteotomy on the posterior ramus. Rigid fixation hardware is placed over the osteotomy, then removed in order to complete the cut. Once the posterior ramus and condyle are removed from the surgical field, the two segments are anatomically reduced and rigidly fixated, as shown in Figs 42.39–42.42. Preplating of the posterior ramus before the osteotomy is completed allows the posterior ramus–condylar unit to be reinserted *in situ* in the intended position without any subtle, unwanted positional changes of the two segments. Figs 42.43 and 42.44 depict the fixation of the symphysis fracture and the postoperative panoramic radiograph, respectively.

Table 42.9 Relative indications for open reduction of condylar fractures.

Medical conditions that are not compatible with maxillomandibular fixation
Bilateral condylar fractures and comminuted midface fractures
Bilateral condylar fractures prevent a stable and reproducible occlusion
Displaced condylar fractures and an inability to use maxillomandibular fixation because of an absence of pre-existing dentures or severe alveolar resorption preventing splint fabrication

Fig. 42.38 Axial CT scan of same patient. Note concurrent symphysis fracture

The undersurface of the TMJ meniscus can be directly examined, and if a repair is necessary it can be performed after the posterior ramus and condyle have been removed. Fig. 42.45 shows the undersurface of a TMJ meniscus after removal of the dislocated condyle. Placement of a moist gauze sponge in the undersurface of the meniscus while the ramus and condyle are being reduced and fixated prevents collapse of the joint space from a clot or surrounding soft tissue edema.

Fig. 42.45 Inferior view of left TMJ meniscus after removal of the dislocated condyle.

Comminuted fractures

The treatment of comminuted mandibular fractures merits special consideration because these fractures are technically more difficult to repair and are associated with a higher rate of complications. Reasons for higher complication rates include: (1) injury to the surrounding tissues from the increased force necessary to create this type of fracture; (2) greater technical difficulty with reduction and stabilization of the fractured segments; and (3) a higher risk for ischemia or avascular necrosis of the bony segments. Despite the rich vascular supply of the maxillofacial skeleton, the smaller bone fragments involved in comminuted fractures may be stripped of their blood supply and become non-viable. The resultant necrosis may lead to either an infection or a non-union of the fracture, which could evolve into a continuity defect. Open treatment of severely comminuted fractures requires enough soft tissue dissection for adequate exposure and visualization, while preserving as much periosteal attachment to the segments as possible so as not to compromise blood supply. In some situations, bone fragments may be replaced as free bone grafts with the application of fixation screws. The use of a locking reconstruction plate is well suited for repair of large comminuted fractures of the mandible. This type of fixation allows the surgeon to bridge the area of comminution and fixate the plate to the proximal and distal intact bone segments. The comminuted fragments can then be reduced and stabilized using positional screws.

Edentulous mandible fractures

Edentulous mandible fractures present a unique and difficult challenge. The mandibular atrophy is both an etiologic factor of the fracture itself and a problematic consideration in the repair of the injury. Previous methods of treatment have included closed reduction of the fracture using the patient's existing dentures with circumskeletal wires, external fixators, internal wires, small plates and screws (both sub- and supra-periosteal), reconstruction plates and screws, and lag screws. As our understanding of fixation methods improves, the ability to manage these clinical challenges has become more predictable.

Several factors may contribute to an unfavorable result in the repair of edentulous mandible fractures. Bradley reported that elderly patients have decreased vascularity to the mandible secondary to the decrease in flow from the inferior alveolar artery.¹⁰⁰ Unlike younger individuals, the blood supply to the edentulous mandible is primarily from the periosteal envelope. An edentulous mandible also has dense, sclerotic bone and decreased osteoblastic activity along the fracture line compared to the dentate mandible. The elderly may also have any number of systemic conditions that affect fracture healing such as diabetes, osteoporosis, vascular disease, renal insufficiency, or

calcium wasting disorders. All of these factors contribute to poor healing potential at the fracture site and an increased rate of a non-union, malunion, or infection.^{101,102}

Most edentulous mandible fractures occur at the body and condyle rather than the angle or parasymphysis regions. The body of the mandible is generally weakest at the mid-body, or saddle, as this is the most significant site for bone resorption. Without dentition to stabilize the segments, the majority of edentulous segments will be significantly displaced from the resultant muscular pull on the smaller and weaker bones.^{101,102}

The degree of atrophy is a factor when choosing a particular surgical option. Closed reduction for edentulous mandible fractures is an effective treatment option, but multiple favorable conditions must exist.¹⁰³ Patients should exhibit adequate bone quantity and quality, minimal swelling, good ridge form, adequate vestibular depth, favorable fracture angulations, good healing potential, and compliance. Immobilizing the segments can be difficult even when the prosthesis fits extremely well. Closed reduction is a reasonable option in the patient who is either unable or unwilling to undergo a more extensive procedure. Longer periods of maxillomandibular fixation are recommended in the elderly patient to ensure adequate healing. Contraindications to maxillomandibular fixation include seizure disorders, psychiatric disorders, significantly altered neurologic states, and significantly compromised pulmonary or nutritional states.

An external fixation device can be used in patients who have grossly infected and/or massively comminuted mandible fractures. It is also useful in those patients with pathologic fractures due to osteoradionecrosis (ORN) or other bony lesions. External fixation is useful in patients with ORN while they receive hyperbaric oxygen therapy in anticipation of surgery that would require periosteal stripping and possible devitalization of bony fragments. External fixation is a very effective therapy despite its limited indications. However, patients will frequently not readily accept the external fixation device due to its unsightliness. The device is often made by securing an endotracheal tube to the transcutaneous fixation pins then injecting an acrylic mixture into the endotracheal tube and allowing it to set. Caution must be used due to the exothermic reaction associated with the acrylic resin. Diligent wound care of the pin sites is critical to prevent an infection, and there must be regular follow-up to evaluate healing and assess the need for debridement.

Open reduction techniques for edentulous mandible fractures must be tailored to the pre-existing morphology of the mandible and severity of the fracture. Transosseous wiring is fraught with complications because of the lack of fracture immobilization and the degree of periosteal stripping required. The use of arch bars with maxillomandibular fixation to reduce

the functional forces on the mandible is not possible, so the wired segments must withstand displacement. Depending on the quality and quantity of bone present and the degree of bone-to-bone contact at the fracture site, the same complications for transosseous wiring may result with the use of small bone plates for fixation of an edentulous fracture.

Open reduction with application of adequate sized rigid internal fixation provides stability and the most predictable healing for edentulous fractures.^{104,105} Typically, this requires the use of at least 2.0 mm bone screws and plates with at least three screws on each side of the fracture. Larger reconstruction plate and screw systems have been used over large areas of the edentulous mandible to ensure rigid fixation of each segment. The disadvantages of this technique include a higher chance for nerve impingement, the need for excessive amounts of periosteal stripping (compromising the blood supply), and the use of larger screws, which can fracture the severely atrophic mandible during placement. Smaller plates and screw systems can be used with less periosteal stripping and more precise screw placement.

In addition to adequate reduction and stabilization of the fractured segments, the successful management of edentulous fractures requires that consideration be given to the amount of bone present. When the mandible is severely atrophic, it is possible that healing will not occur even if open reduction and internal fixation principles are properly applied. In these rare circumstances, the treatment consists of concurrent bone graft reconstruction at the time of fracture repair. This methodology is also appropriate for patients presenting with a non-union of an edentulous fracture. In most cases definitive prosthetic reconstruction is delayed until complete bony healing has occurred. Some authors advocate early reconstruction with bone grafts and osseointegrated implants.¹⁰⁶

Pediatric mandible fractures

The bones of the midface are relatively protected early in life. Thus, midfacial fractures are rare in infants and young children.¹⁰⁷ In contrast, the mandible is more exposed and prone to injury in all age groups. Fracture patterns depend on the level of mandibular development. Compression fractures of the condyle are common in early childhood due to a short thick condylar neck and high cancellous to cortical bone ratio. The risk of condylar neck fractures increases as the child grows and the condylar neck elongates.

The vascular supply of the mandible arises from the periosteum and an endosteal supply, i.e. the inferior alveolar artery. The blood supply from the endosteal route is more prominent in children, while the blood supply from the periosteum is more important in adults.¹⁰⁸ For these reasons the healing potential of pediatric bone is greater, affording flexibility when

using closed techniques to repair mandibular fractures that might result in a non-union in an elderly patient.

Children comprise approximately 5% of all mandibular fractures. Anatomic differences between the pediatric and adult mandible influence the occurrence and pattern of fractures. Pediatric patients often sustain either a minimally displaced or greenstick fracture of the mandible because of the greater elasticity of the mandible and the presence of developing tooth buds. Mandibular fractures in children should raise the clinician's suspicion for concomitant injuries. Kaban *et al.*¹⁰⁹ reported that 76% of pediatric patients with a mandibular fracture also had other associated injuries.

Physical findings on pediatric trauma patients are similar to those of adults: malocclusion, limited opening, deviation on opening, tooth-related injuries, intraoral ecchymosis or lacerations. Chin lacerations often accompany condylar fractures from a fall. The imaging study of choice in the evaluation of pediatric mandibular fractures is the panoramic tomogram. When circumstances do not allow for such an image, then either a mandibular plain film series or a CT scan of the maxillofacial bones can be obtained.

Non-displaced fractures in a pediatric patient who is able to understand and comply with specific instructions may be managed conservatively with a liquid diet and close observation. However, most other fractures, especially those that occur closer to adolescence, are treated with a 2-week period of immobilization.¹¹⁰ Placement of interdental wires and arch bars on primary teeth or newly erupting permanent teeth is difficult and often not feasible because these teeth do not have a sufficient cervical height of contour. Thus, immobilization must take place in the form of either an acrylic lingual splint and circummandibular wires or maxillomandibular fixation with circumsketal wires. Postoperative physiotherapy is essential to regain a complete range of motion. If early mobilization is not undertaken, then the patient may experience muscle atrophy, joint hypomobility, or, in extreme cases, ankylosis. Most pediatric patients avoid mandibular growth disturbances with conservative therapy alone following condylar fractures.^{33,34} If a future mandibular growth disturbance is of concern, the prevailing opinion is to allow remodeling to occur then reassess mandibular growth after the facial skeleton has matured.

Conclusions

The successful management of any mandibular fracture requires a thorough understanding of dental and mandibular anatomy, occlusion, related biomechanical forces, and articulations. Most mandibular fractures can be treated adequately with closed techniques.¹¹¹ More contemporary management relies on open techniques that are based on a proper

diagnosis and classification, anatomic reduction, stabilization with respect to pre-existing occlusal relationships, and appropriate rigid internal fixation techniques. Although the subject of mandibular fractures has been one of the most studied areas in oral and maxillofacial surgery, few prospective data exist regarding the outcome of the various treatment modalities. Retrospective studies offer some evidence that certain open techniques have independently done better than others, but more continued research in materials and outcomes will further refine the treatment of mandible fractures and improve the quality of life for these patients.

Chapter 43

Transoral Endoscope-assisted Treatment of Displaced Condylar Mandible Fractures

Ralf Schön and Rainer Schmelzeisen

Transoral endoscope-assisted treatment, using an angulated drill and screwdriver, is an alternative to extraoral approaches for the surgical management of displaced condylar fractures; it has been developed in some centers over recent years. Facial nerve injury and visible scars are avoided using the transoral endoscope-assisted approach. Today's indications for the transoral endoscope-assisted surgical approach are presented as well as recent refinements of this surgical technique for the treatment of condylar fractures.

Summary, 909

Fractures of the mandibular condyle are common and account for 9–45% of all mandibular fractures.^{1,2} Shortening of the ascending ramus in displaced condylar fractures causes functional impairment with malocclusion, limited range of motion of the mandible, and development of a contralateral open bite in unilateral and an anterior open bite in bilateral fractures. Surgical reduction with an extraoral approach remains controversial due to possible complications, such as the risk of facial nerve injury and creation of visible scars, and for this reason non-surgical treatment is still most widely employed.^{3–7} However superior functional results are reported after surgical anatomic reduction and fixation for displaced and dislocated condylar fractures, compared to non-surgical treatment.^{5,7–9}

The transoral approach for the reduction of condylar mandible fractures has been demonstrated to reduce the risk of facial nerve injury and does not

leave any visible scars.^{10–13} However, it is a technically demanding method with limited visibility of the fracture site and has not gained wide acceptance.

Due to recent development of endoscopic instruments, especially the chip camera technology, endoscope-assisted techniques have become more widely accepted in oral and maxillofacial surgery, such as in temporomandibular joint (TMJ) arthroscopy and sialoendoscopy. Superior visibility can be achieved through limited incisions with the transoral approach for endoscope-assisted surgical reduction of mandibular condyle fractures.^{13,16,17}

Initially the transoral endoscope-assisted approach was only recommended for laterally displaced subcondylar fractures and satisfying results were obtained.^{13–15} Following the good initial results and after a steep learning curve, the transoral endoscope-assisted approach has also become a routine procedure for the treatment of medially displaced and dislocated condylar fractures over the last decade.^{16,17}

Indications

The indication for surgical treatment of condylar mandible fractures is displacement and dislocation of the fractures causing malocclusion and functional impairment with a limited range of motion. A contralateral open bite is typical for unilateral and an anterior open bite for bilateral condyle fractures, with displacement demonstrating shortening of the height of the ascending mandibular ramus. The size of the fragment is a limiting factor for surgical treatment of condylar neck fractures, and surgical treatment is only performed when at least two screws can be anchored in the condylar fragment. For this reason high condylar fractures, such as intracapsular and condylar head fractures, are treated non-surgically. Edentulous patients are treated with surgical reduction and fixation only when they present with severe pain on motion in displaced subcondylar and low condylar neck fractures.

Contraindications

Non-surgical treatment is recommended in undisplaced condylar fractures without functional disturbances, in high condylar neck fractures, intracapsular and condylar head fractures, in displaced fractures without functional impairment, and also in the majority of pediatric patients and edentulous patients. Non-surgical treatment can be followed by functional treatment with physiotherapy or orthodontic devices, such as an activator, to reduce functional impairment.¹⁸

Pre-, intra-, and postoperative evaluations

The type of fracture, degree of displacement, and result of reduction can be evaluated preoperatively, intraoperatively, and postoperatively with the endoscope and by Townes' and panoramic radiographs, and in selected cases by computed tomography (CT) or cone-beam CT (Figs 43.1–43.6). If intraoperative cone-beam CT scanning is available, control of the reduction can be performed in the operating room. However, due to the precise endoscopic control of the

Fig. 43.1 Townes' and panoramic radiographs preoperatively (a, e) and postoperatively (b, c, d) demonstrate a displaced condylar fracture with shortening of the ascending ramus before and after endoscope-assisted transoral anatomic reduction and osteosynthesis. The surgical correction of the shortening of the ascending ramus is demonstrated (b, c, d). Maxillomandibular fixation was used intraoperatively for the osteosynthesis of an additional mandibular fracture.

Fig. 43.2 (a–c) Preoperative panoramic radiograph, and an axial and coronal view of a CT scan demonstrate a 90° dislocated fracture of the condylar neck in a patient who also sustained a displaced bilateral midfacial fracture. (d, e) Following the open reduction and fixation (ORIF) of the right zygomatic complex, a Le Fort I fracture, and a left alveolar process fracture, the displaced condylar neck fracture was reduced and fixed by transoral endoscope-assisted approach.

fracture reduction, intraoperative imaging is only indicated in selected cases.

Fig. 43.4 demonstrates the endoscope-assisted reduction and fixation of condylar fractures, performed via limited transoral incision using 30° and 45° angled endoscopes and a Xenon light source (Karl Storz®, Tuttlingen, Germany).

Surgical technique

The transoral approach for endoscope-assisted reduction and osteosynthesis of displaced and dislocated

condylar mandible fractures should be performed using an angulated drill and screwdriver.

Prior to the transoral incision, local anesthesia is infiltrated in the vicinity of the fracture and the area of the surgical approach to obtain a blood-free optical cavity. Bleeding into the optical cavity is usually minimal due to infiltration of local anesthesia. The limited incision is made along the anterior aspect of the ascending mandibular ramus, comparable to the cranial part of the incision for sagittal split osteotomy (Fig. 43.4d).¹⁷ The mucoperiosteum is then elevated subperiosteally and the ascending mandibular ramus is exposed. The masseter muscle is not dissected by

Fig. 43.3 (a) The endoscopic view demonstrates a medially displaced fracture of the mandibular condylar process. (b) By forward and downward rotation of the mandible, the TMJ area is distracted and the fragment is reduced in a lateral displacement before anatomic reduction and fixation. (c) Transoral osteosynthesis is performed using an angulated drill and screwdriver. (d) Note a butterfly fragment is missing at the posterior border. (e, f) The butterfly fragment is fixed with an adaptation plate before a more rigid plate is placed at the posterior aspect of the ascending mandibular ramus. Fracture reduction including the realignment of butterfly fragment is recommended to allow for a load-sharing situation, to reduce the stress of functional loading on the osteosynthesis. Townes' radiographs preoperatively (g), postoperatively (h), and a panoramic radiograph (i) demonstrate the displaced fracture before and after the minimally invasive reduction and fixation.

the subperiosteal approach to avoid bleeding in the optical cavity.^{13,16} Good visibility is obtained during the surgical approach, using a head light with a xenon light source (e.g. Karl Storz®, Tuttlingen, Germany).

Localization of the fracture site and of the displaced fragment is performed using the endoscope (Fig. 43.5d). Muscle relaxation is mandatory to allow reduction of the fracture. To distract the TMJ region, pressure is applied to the posterior teeth of the mandible and the mandible is rotated forward. Maxillomandibular fixation (MMF) is not recommended during the fracture reduction. Due to the manipulation of the mandible to allow for fracture reduction, additional mandibular fractures should be fixed first to prevent further fracture dislocation and injury of the inferior alveolar nerve (Figs 43.1, 43.4, 43.5, and 43.6). MMF is only performed intraoperatively for the fixation of additional mandibular fractures and released before the open reduction and internal fixation (ORIF) of the condyle fracture is performed. In medially displaced fractures, the fragment is reduced in a lateral position to allow miniplate fixation (Fig. 43.3a, b). This procedure may be difficult and can be facilitated in selected cases by inserting an elevator subperiosteally at the lingual aspect of the ascending ramus. The instrument has to be inserted

cranial to the mandibular foramen to push the fragment into a lateral position. Subperiosteal insertion of the elevator is necessary to avoid damage to the maxillary artery.

The first plate is then placed in the cranial aspect of the fracture with visual control of the incisura semilunaris, using an adaptation plate of the 1.5 or 2.0 compact system (Synthes) usually using screws 4 mm in length (Figs 43.3c and 43.5d). Insertion of the first screw together with the plate is performed using an angulated screwdriver with a plate screw holding device (Figs 43.3c and 43.5f).^{13,17} No additional plate-holding instrument is used.

After the first screw is anchored cranial to the fracture line, the fragment is pulled anteriorly and caudally using a nerve hook or a Mitchell's trimmer inserted in an empty inferior hole of the plate to reduce the fracture (Figs 43.3d and 43.5e). When the fracture reduction proves to be satisfactory by endoscopic control, the plate is fixed with a second screw close to the fracture (Figs 43.3d and 43.5e). Care should be taken that no soft tissue is entrapped in the fracture. Then the quality of the fracture reduction is double checked endoscopically along the fracture line and at the posterior aspect of the ascending ramus (Figs 43.3d, e; 43.4c; 43.5e, g; 43.6d). After the fracture

Fig. 43.4 (a, b) Panoramic radiograph and Townes' view demonstrate a bilateral condylar fracture and an additional oblique left paramedian mandibular fracture. (c) Endoscopic view shows the left condylar fracture site after reduction and fixation using two miniplates. The posterior aspect of the ascending mandibular ramus is viewed endoscopically and anatomic reduction is achieved. (d) Note the limited transoral incision for the endoscope-assisted transoral approach after wound closure. (e) Postoperative panoramic radiograph. Due to the moderate displacement of the left condylar process fractures a non-surgical treatment by maxillary-mandibular fixation would have been an alternative treatment option. However, as surgical treatment was indicated for the mandible fracture the fixation of the condyle fractures was performed to avoid intraoperative displacement of the fracture due to reduction of the mandibular ramus and right condylar fracture, and to allow immediate function without postoperative maxillary-mandibular fixation. The time for open reduction and fixation of the bilateral condyle fractures was 80 minutes. (f, g) Sagittal view of cone-beam CT scan 6 weeks postoperatively demonstrates stable anatomic fracture reduction.

Fig. 43.5 (a, b) The degree of displacement and location of a bilaterally displaced condylar fracture is demonstrated in an axial view and a 3D reconstruction of a CT scan. An anterior open bite is noted due to the bilateral shortening of the ascending ramus. Mandibular maxillary fixation (MMF) for the fixation of traumatized teeth and for an initial non-surgical treatment of the bilateral condyle fractures and lag screw osteosynthesis of a paramedian mandibular fracture was performed, as prolonged immediate surgery was contraindicated due to concomitant chest injuries. The transoral endoscope-assisted treatment of the bilateral condylar fractures was performed at day 7 after the injury. (c) The intraoperative endoscopic view shows laterally displaced right condylar fracture. (d) Intraoperative endoscopic view shows the placement of the first plate with one screw in the condylar fragment. (e) By pulling the plate anteriorly the fracture is reduced. (f, g) Fixation of the second plate along the posterior border of the mandible is performed using an angulated drill and screwdriver under endoscopic control. (h, i) The postoperative panoramic and Townes' radiographs demonstrate the anatomic reduction and fixation using miniplates. (j) The postoperative result after elective removal of the miniplates 1 year after surgery shows a stable result.

Fig. 43.5 (cont'd) (k) 3D reconstruction of the preoperative CT scan shows a retruding chin point due to backwards rotation of the mandible caused by bilateral shortening of the ascending ramus due to the pull of the temporalis and masseter muscles. (l) The chin projection has been corrected after bilateral anatomic fracture reduction.

has been simplified with the first adaptation plate, the second, more important plate can be precisely placed along the posterior aspect of the ascending ramus, where strong cortical bone allows for anchorage of the plate using screws 6 mm in length. The first screw of the posterior plate is placed in the fragment close to the fracture line. After anchorage of the posterior plate with one screw, the plate is pulled caudally and reduction at the posterior aspect is controlled using an angulated endoscope. If the reduction is not satisfactory, the anterior screw of the first plate may be loosened or removed. The reduction can be improved using a nerve hook or Mitchell's trimmer to pull the posterior plate antero-caudally. The second screw hole of the posterior plate can be drilled away from the fracture site to gain some compression to improve the fracture reduction. When the fracture reduction is satisfactory, osteosynthesis is completed with screws in a neutral position (Figs 43.3f; 43.4c; 43.5f, g; 43.6d).

Occlusion is checked at this stage. In general when precise fracture reduction is demonstrated endoscopically, preinjury occlusion is re-established. The two-plate technique allows for better fracture control and facilitates the precise placement of the most important plate along the posterior mandibular ramus (Figs 43.3e and 43.5f). Placement of the posterior plate as the first plate may limit the visibility of the posterior aspect of the mandibular ramus (Fig. 43.3f) and may cause an inferior anatomic reduction. A dental mirror may also be used to check fracture realignment after placement of the posterior plates (Fig. 43.6d). At the posterior border, preferably a 2.0 AO/ASIF non-compression miniplate (Synthes® Paoli, PA, USA, # 443.451) is used (Figs 43.1, 43.2, 43.4, and 43.6). This plate has been designed for the osteosynthesis of the midface and is less rigid than 2.0 mandible plates. The plate therefore adapts more easily to the bone surface than the rigid mandible plates when the screws are tightened. This proves to be beneficial for exact fracture reduction in the area of the mandibular condyle, as precise bending of the plates may be difficult. Dislocation at the fracture site when tightening the screws is avoided by using the less rigid plates.

In condylar neck fractures, two-plate osteosynthesis with the modified 2.0 mm zygoma AO-ASIF miniplate (Synthes® Paoli, PA, USA, # 443.451) along the posterior border of the ascending ramus is the authors' first choice of treatment.¹⁷ No plate loosening or plate fractures have yet been encountered when this plate has been used. Additional 1.5 or 2.0 AO-ASIF adaptation miniplates (Synthes®, Paoli, PA, USA) are placed in more than 70% of the authors' patients to counteract the demanding mechanical forces in the area of the mandibular condyle when immediate loading is allowed. In some cases the placement of a modified zygoma plate is not possible because of the limited bone surface (Fig. 43.5). The 2.0 compact (Synthes®, Paoli, PA, USA) four-hole plates with space have been used as the authors' second choice (Fig. 43.5). Good visualization for control of reduction and fixation can be achieved endoscopically. An angulated drill and screwdriver facilitate osteosynthesis; the insertion of the first screw together with the plate has been especially helpful (Figs 43.3, 43.5).^{13,16,17} Osteosynthesis was performed in all patients by a transoral approach only, without transfacial incisions for screw insertion. Angled elevators and reduction-manipulation forceps for condylar fractures, along with long retractors and periosteal elevators (Synthes® Paoli, PA, USA, AO Development Institute, Davos, Switzerland), have proved to be useful for the reduction of displaced fractures.¹⁵⁻¹⁷

Postoperative course and long-term results

Immediate postoperative movement is allowed in all patients and a soft diet is recommended for the first 10 days after surgery. Results show precise anatomic reduction and restoration of the vertical height of the ascending mandibular ramus are achieved, without malocclusion, in all patients. After 3 months and after 1 year of follow-up, mouth opening in all patients is generally more than 40 mm without deviation on opening and lateral excursion is not limited.¹⁵ Good TMJ function and an inconspicuous intraoral scar

Fig. 43.6 (a–c) A severely dislocated mandibular ramus and bilateral condyle fracture is demonstrated in the preoperative imaging by panoramic radiograph and CT scan. Lateral displacement of the right subcondylar fracture and medial displacement of the left condylar fracture is noted in the axial and coronal CT scan view. (d) The endoscopic view shows the anatomic reduction of the left condylar fracture. Using a dental mirror posterior to the posterior border of the ascending ramus, the fracture site is visualized after ORIF. (e, f) Postoperative panoramic and Townes' radiographs demonstrate the postoperative result.

without signs of facial nerve damage are seen. There have been no signs of TMJ dysfunction or pain in the TMJ.¹⁵

Removal of osteosynthesis material is rarely performed. In selected cases when a limitation of the range of motion was noted 1 and 3 months after surgery, functional treatment using physiotherapy and an orthodontic appliance has been recommended.¹⁸ Good TMJ function with mouth opening of more than 40mm without deviation, and with preinjury occlusion and TMJ motion can be expected after 12 months.

Surgical vs non-surgical treatment of mandibular condyle fractures

Non-surgical treatment of condylar mandible fractures is most widely performed even in displaced and dislocated fractures of the condylar mandibular process. Open bite deformity or malocclusion may occur following non-surgical treatment due to shortening of the ascending ramus.^{8,16,17,19} Functional treatment may lead to satisfying results. However the patient must be compliant and a treatment period of 6–

12 months has to be taken into account to achieve satisfying functional results when physiotherapy and/or activator treatment is performed.¹⁸ To avoid the long treatment period and complications noted in patients with displaced fractures, open anatomic reduction may be beneficial and allow the patient to achieve early function.^{4,5,7–9} Even in moderately displaced condylar fractures, ORIF should be considered when additional mandibular fractures or bilateral condyle fractures with only moderate displacement on one site and displacement or dislocation on the other side may be present. Due to the manipulation for MMF and ORIF of the mandibular fracture, further displacement of the condyle fracture may occur intraoperatively. In such cases, intraoperative imaging by cone-beam CT scan is helpful to decide if ORIF is indicated in the moderately dislocated condyle region. To avoid displacement and to allow for early function, ORIF should be considered, even for moderately displaced condyle fractures, although non-surgical treatment may be possible to avoid MMF and to allow for early function (Fig. 43.4).

However, the indication for surgical reduction vs non-surgical treatment of displaced condylar fractures remains controversial in maxillofacial surgery

because of possible surgical complications, such as damage of the facial nerve and creation of visible scars when surgical treatment is performed.^{4,5-8}

The role of endoscope-assisted transoral techniques

To minimize the risk of the described complications, endoscope-assisted techniques using extraoral and transoral incisions have been described for various indications in the craniomaxillofacial area.²⁰⁻²⁴ The extraoral approach for condylar fractures was previously described as the preferred approach for medially displaced and comminuted condylar fractures and the transoral approach for laterally displaced fractures.¹³ Following the first promising results, the authors have also been using the transoral approach for medially displaced and dislocated condylar fractures routinely for the past decade. Condylar neck fractures have been treated by the same approach, when at least two screws could be anchored in the condylar fragment.^{15,16}

The use of the two-plate technique allows for precise fracture reduction under intraoperative endoscopic control. The precision of the fracture reduction in this mechanically demanding area with limited bone surface to realign is most important for achieving stable long-term results, without screw loosening and plate fractures. When the reduction is not adequate, fatigue fractures of the hardware and loosening of the screws may be encountered. Plate fractures following ORIF of condyle fractures have been reported with an incidence of up to 35%.²⁴ Before endoscope-assisted ORIF was performed in the authors' department about 10% of plate fractures were noted following ORIF in condyle fractures. Using the endoscope-assisted technique, less than 2% of failure of osteosynthesis has been noted in the authors' experience over the last 8 years.

Training

Intensive training in endoscope techniques is mandatory before the endoscope-assisted transoral approach for the treatment of condylar fractures can be performed. A steep learning curve with significant reduction of operating time has been noted when using the endoscope-assisted technique.^{13,15-17,25} After such training, the mean operating time for the minimally invasive transoral treatment at the authors' center today is 1 hour 05 minutes.

Summary

The endoscope-assisted transoral approach has developed in recent years and is today a reliable surgical approach for displaced and dislocated condylar

fractures; this is reflected in increasing acceptance of this technique.²⁶⁻³¹ In non-dislocated fractures and fractures of the condylar head, non-surgical treatment still remains the treatment of choice.³²

Chapter 44

Soft Tissue Trauma

Bethany Serafin, Paul Koshgerian, and Richard H. Haug

A soft tissue injury is one of the most common problems treated in the emergency rooms and the facial region is an esthetically sensitive area with a complex variety of tissues. In this chapter, current principles of treatment for the different types of soft tissue injuries in various locations in the orofacial region are systematically presented. Factors of importance for successful wound healing are thoroughly discussed.

Introduction

Although the number of lacerations treated in emergency departments has actually decreased over the past decade, traumatic laceration remains one of the most common problems treated in the emergency room, with 28% of those being to the face.¹ According to a 2004 study conducted by the National Center for Health Statistics, there were an estimated 2.5 million facial lacerations treated in United States (US) emergency rooms in that year alone.¹ Singer *et al.* compared demographics and characteristics of lacerations presenting to the emergency department over 10 years from 1992 to 2002.¹ Their findings of lacerations, not limited to the face, show that lacerations present slightly more frequently at weekends and during the spring and summer months. Furthermore, more lacerations present between noon and 10 pm with two thirds of the patients being male, one third of the

patients being under the age of 18, and three quarters being white.

Facial lacerations occur more commonly in children, with boys between the ages of 4 and 7 years, having a disproportionately larger number of lacerations. According to a study by Mack *et al.*, in the US, every 90 seconds a child 1 year of age or younger, is treated in the emergency department for non-fatal, accidental injury.² Contusions and abrasions top the list of injuries treated; and those contusions and abrasions, in addition to laceration, hematoma, puncture and foreign body wounds, occur most frequently to the head or neck.² Soft tissue injuries outnumber fractures in children who sustain facial trauma due to the relative elasticity of bone at a young age. A study by Gassner *et al.* reviewed 3385 cases of pediatric cranio-maxillofacial trauma sustained over a 10-year period.³ Causes of these soft tissue injuries were most frequently traffic accidents followed by sports and vio-

lence, followed by play.³ As in adult soft tissue trauma, the peak of all types of injuries in children occurs during the spring and summer months. Children represent a special population for soft tissue injuries due to their quick healing and tendencies toward hypertrophic scar and keloid formation.

Maxillofacial trauma results in a multitude of consequences for the patient, as well as their family members and society as a whole. While data specific to soft tissue injury are lacking, studies of maxillofacial injury in general have shown that trauma has significant and often unrecognized psychosocial and economic impact.

There exists in maxillofacial injury the potential for great psychological disability. Post-traumatic psychopathology (PTP) is a spectrum of disease, ranging from short-term anxiety to post-traumatic stress disorder at the extreme end. While few studies have examined the extent of psychopathology following facial injury, research has shown that psychological morbidity is common, it is persistent throughout the follow-up period, it can become chronic, and the clinical severity of the injury does not correlate well with the development of psychopathology.^{4,5} When maxillofacial trauma leads to post-traumatic psychological disturbance, a vicious cycle has then been created because the resulting psychopathology also has a significant impact on physical recovery from injury. There is a biological basis for impaired recovery and wound healing through prolonged inflammatory response when PTP complicates recovery. Also, due to its impact on compliance with treatment and follow-up, PTP contributes to poor recovery.^{4,6}

The financial impact of injury is enormous. In addition to the immediate and long-term cost of care, injury also causes a tremendous loss in productivity, a cost that society ultimately bears. The productivity loss due to injury includes lost wages, lost benefits, loss of marketable goods and services, as well as loss of the ability to perform daily responsibilities at home. The dollar value of productivity loss for injuries that occurred in the US in 2000 is an estimated \$326 billion which far exceeds that of the \$80.2 billion in cost for the medical treatment related to these injuries.⁷

General principles of management

Assessment

During examination of any facial injury, several features and characteristics must be noted and made part of the medical record. The mechanism of injury and time of occurrence, as well as witnessed accounts should be recorded. Mechanism of injury will provide information about any potential foreign bodies that need to be removed or contaminants that may affect wound healing. The circumstances of the injury should also be elicited within the history. Knowing

an injury is work-related, an act of domestic violence, or an assault is important for the medico-legal aspect of the patient's care. Any treatment of the wound already rendered prior to formal evaluation should be ascertained.

Knowing the tetanus immunization status of the patient is important. Past medical history including a list of medications and allergies should be reviewed and vital signs should be measured. It is well known that certain comorbidities and medications adversely affect wound healing and may necessitate a change in the normal course of treatment.

A primary survey of the patient will reveal the patient's airway status, neurologic function, and any other serious injury to the chest, abdomen or extremities. Once life-threatening injuries have been ruled out, an assessment of the wounds in question can be performed. Physical examination includes inspection of the area noting the location, size, and shape of the wound. Limitation of function and involvement of nerves, vessels, muscles, or other vital structures should also be noted. Presence of foreign bodies, contamination, associated fractures or hematomas, non-vital tissue or, in the case of an old injury, presence of infection should be determined. Noting all of these characteristics upon examination will allow the practitioner to develop a thorough, well devised plan for repair.

Timing of repair

While not every traumatic wound presents with a critical load of bacteria necessary to cause infection, every traumatic wound should be considered contaminated. This does not mean, however, that traumatic wounds of the face cannot be closed primarily, even after considerable time delay.

With regard to infection rate, timing of repair is critical. Wounds that are cleaned and closed in a timely manner have less chance of developing wound infection. The role of the critical load of bacteria (100 000 bacteria per gram of tissue) is discussed elsewhere in this chapter; however, this number has been established as a threshold for wound infection. Wounds with inoculums above this number have a 95% chance of becoming infected.⁸ Wounds with less than 10^5 bacteria per gram of tissue will heal uneventfully. In a study of wounds presented to the emergency room, Robson *et al.* observed that wounds less than 2.2 hours old had 10^2 bacteria per gram of tissue – well below the critical number for infection.⁸ Wounds 3 hours old had 10^2 – 10^6 bacteria per gram of tissue and wounds more than 5 hours old consistently held more than 10^6 bacteria per gram of tissue – well above the threshold for infection.

Ideally, wounds of the head and neck are repaired in order for healing to occur by primary intention. This type of healing takes place quickly and with minimal scar formation. Some arbitrary guidelines have been developed and the consensus is that uncompli-

cated clean lacerations of the face can be closed primarily up to 24 hours after injury.⁹ Trott recommends that if the wound, irrespective of time after injury, can be debrided and cleaned such that the wound appears fresh and bleeds slightly, it can be closed primarily.¹⁰

A more prolonged healing process, healing by secondary intention, occurs when a wound is left open and allowed to heal from the inside out by way of a granulation tissue base with subsequent epithelialization and contraction. It is rare to have this type of healing from traumatic wounds on the face.

Delayed primary closure is a method of management of dirty or infected traumatic wounds or wounds that have gone unrepaired for a considerable amount of time. These wounds are converted to fresh wounds through debridement and removal of tissue edges and then covered loosely for several days. After this short period of time the wound can once again be debrided and then closed if no infection is evident.

Antibiotic and tetanus prophylaxis

Non-bacterial contributors to infection

There are several non-bacterial contributors to wound infection. Torn and crushed tissue is likely in traumatic injury to the maxillofacial region. Dead, devitalized tissue within a wound contributes to colonization and subsequent infection.

The impairment of vascular supply to tissue is another contributor to wound infection. While the skin of the face receives a disproportionately large amount of blood, slow healing of a wound in this area can still result when conditions that contribute to poor circulation are present. Systemic conditions such as diabetes or arteriosclerosis or local factors such as excessive wound tension or thrombosis cause impairment of local circulation and thus increased risk of infection.

Location of the wound is a factor in wound infection. Injuries of the face are less likely than other areas of the body to become infected; however, the likelihood is increased if that wound involves the oral cavity.

Foreign bodies such as metal, wood, glass, grass, dirt, etc. harbor organisms and contribute to wound infection. Deep sutures also act as foreign bodies and accumulations of blood and fluid within a wound can act to harbor organisms, delay healing, and contribute to infection.

Abnormalities in immune function, both local and systemic, compromise the healing of tissue injury. Leukocyte dysfunction and inflammatory response reduction have various causes, including immunodeficiency diseases, chronic steroid use, malnutrition, radiation therapy, and burns. Heightened immune response in the form of allergy can also add to the development of wound infection.

Bacterial contributors to infection

There is no convincing evidence that antibiotics are useful for preventing infections in simple lacerations.^{11–13} However, there are times when antibiotic administration should be considered and this coverage should be given as soon after injury as possible. Studies have shown a “golden period” for the effective use of antibiotics within about 3 hours after injury.^{8,14} Antibiotics are indicated in certain circumstances, some of which include: patients with lymphedema, patients who are prone to bacterial endocarditis, grossly contaminated wounds, ear lacerations, bite wounds, and in patients with systemic disease that compromises healing, such as diabetes or cirrhosis.

The acutely contaminated wound presents a challenge to wound management and healing. The goal is to decrease the bacterial inoculum to below the critical level. This can be accomplished by sharp debridement of necrotic and devitalized tissue. Intermittent high pressure irrigation with a pulsating jet lavage system can assist in the removal of debris and bacteria. For grossly contaminated wounds, the repairs usually occur in the operating room. Systemic antibiotics are of little value unless given within the 3-hour time window after injury. Unless given immediately upon presentation to the emergency department, it is unlikely that antibiotics will be administered within that “golden time” period. And when in doubt, the wound can be left open, packed, and delayed closure planned.

Tetanus prophylaxis

Tetanus is a disease that occurs when oxygen-poor tissue, such as that of a wound, gets inoculated with *Clostridium tetani* spores which then germinate to bacilli and produce a potent neurotoxin. Tetanus presents as generalized muscle contractions that can involve the respiratory system and ultimately lead to death. The reported cases of tetanus have declined considerably since the use of widespread vaccination; however, during the time between 1990 and 2001, 534 cases were reported in the US, and tetanus has a high morbidity.¹⁵ Older adults have a higher incidence of tetanus, possibly due to the failure of initial immunization.¹⁶

During history taking, the tetanus immune status of the patient should be established. It should be determined whether or not the patient has had an initial tetanus immunization and, if so, when was the date of the last tetanus toxoid booster. The Advisory Committee on Immunization Practices (ACIP) is a committee of the Center for Disease Control and gives the guidelines for the administration of tetanus prophylaxis (Table 44.1). Recently, the preparation of tetanus toxoid, which was combined with diphtheria toxoid (Td), has incorporated a pertussis vaccine and this formulation is designated Tdap. In the USA, one Tdap product, ADACEL® (sanofi pasteur, Toronto,

Table 44.1 Guide to tetanus prophylaxis in routine wound management. History of adsorbed tetanus toxoid (doses)	Clean, minor wound		All other wounds ^a	
	Tdap, Td or DTaP ^b	TIG	Tdap, Td or DTaP ^b	TIG
Unknown or <3	Yes	No	Yes	Yes
≥3	No ^c	No	No ^d	No

^a Such as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^b Tdap is preferred to Td for adolescents and adults aged 11–64 years who have never received Tdap. Td is preferred to TT for adults who received Tdap previously, or when Tdap is not available. DTaP is indicated for children <7 years old.

^c Yes, if >10 years since the last tetanus toxoid-containing vaccine dose.

^d Yes, if >5 years since the last tetanus toxoid-containing vaccine dose.

Tdap, tetanus toxoid combined with diphtheria and a pertussis vaccine; Td, diphtheria toxoid; TT, tetanus toxoid; TIG, tetanus immune globulin; DTaP, diphtheria, tetanus and pertussis vaccine.

Ontario, Canada) is licensed for use in persons aged 11–64 years as a single dose active booster vaccination against tetanus, diphtheria, and pertussis. Another Tdap product, BOOSTRIX[®] (GlaxoSmithKline, Rixensart, Belgium), is licensed for use in adolescents but not for use among persons aged ≥19 years.¹⁵ ACIP recommends that adults receive a tetanus toxoid-containing booster vaccine every 10 years, or Tdap and tetanus immune globulin (TIG) as part of wound management, to maintain protective levels of tetanus antitoxin. For adults who have already been vaccinated with Tdap, Td preparation should be used if a tetanus toxoid-containing vaccine is indicated for wound care. Tdap vaccination should be deferred in the case of acute illness until that illness resolves or in cases of unstable neurologic conditions such as cerebrovascular accident (CVA) or encephalopathies.

Tissue handling

Several principles apply to tissue handling that can affect the healing process. Gentle handling of all tissue and proper use of retractors, tissue forceps, and sutures promote faster healing. Sutures tied too tightly around the edges of the wound increase the risk of infection.¹⁷ The presence of dirt, glass, or other foreign material increases the risk of infection. Removal of all foreign bodies and non-vital tissue is necessary

prior to closure. Necrotic tissue should be removed; however, skin and dermis should be conserved as much as possible. Often, dusky skin which initially looks devitalized may go on to heal. Later revision will benefit by having as much skin as possible preserved at the time of initial repair. Adequate hemostasis within the wound not only makes exploration and assessment easier, but also decreases the rate of wound infection and delayed healing. Single-bleeding vessels should be ligated, but blind clamping within the wound may lead to excessive tissue damage and prolonged healing time. Persistent oozing may be treated with direct gauze pressure held firmly for 5 minutes. Epinephrine-soaked gauze or other hemostatic agents such as synthetic methylcellulose foam or sheets may also help to control bleeding. The wound should be kept moist throughout repair. Long cases of repair without wound irrigation may cause desiccation of the tissue leading to prolonged healing time.

Another principle in wound handling is elimination of wound dead space prior to closure. If layered closure does not eliminate all the potential for air or fluid accumulation between the tissue layers in clean, non-contaminated wounds, drain placement or pressure dressing should be considered. In contaminated wounds, deep closure increases the risk of infection.¹⁷ Finally, when closing the wound, tension on the skin should be eliminated. Deep subcutaneous sutures and slight undermining of wound edges help to accomplish this. When closing tension is high, the likelihood of ischemia, tissue necrosis, and dehiscence is high as well.

Instrumentation

Absorbable sutures

As discussed earlier in this chapter, facial lacerations in the pediatric population are frequent. Due to the difficulty in removing sutures in a young patient and need for an additional visit to the provider, absorbable sutures have become an alternative to the nylon sutures traditionally used in repair of facial lacerations. Cosmetic outcomes, complication rates, and parental satisfaction have been measured in studies of children who have sustained facial lacerations and there was no significant difference between subjects who received standard wound closure with non-absorbable sutures vs absorbable sutures.^{18–21}

Tissue adhesive

Cyanoacrylate-based tissue adhesives have been used for laceration repair outside the US for many years; however, these have only been recently approved for use within the US, with 2-octyl cyanoacrylate (Dermabond, Ethicon Inc., Somerville, NJ) leading the way. Tissue adhesives are quick, easy to use, and painless because they do not require the use of local

anesthesia, and they also eliminate the need for suture removal. The contraindications for their use outnumber the indications; however, for repair of simple traumatic lacerations, tissue adhesive may be a viable option.

Proper case selection is the key to successful outcome. It is important to avoid getting adhesive between the wound edges in order to avoid wound tattooing from the blue pigments within the adhesive. This is most likely to occur in cases where the laceration is stellate or avulsive. A rare complication of the use of Dermabond reported in the literature is a blue discoloration of a scar after the use of Dermabond to repair a stellate laceration where it is presumed that the wounds were inadequately approximated.²²

The rates of wound infection and dehiscence as well as cosmetic score for closure with tissue adhesive are comparable to those of suture closure.²³ While follow-up costs (physician fee and lost wages) are minimized with the use of tissue adhesive, the cost-effectiveness of the use of tissue adhesive compared to traditional suture closure methods is controversial.²³⁻²⁵

Staples

Skin stapling devices have primarily been used in closing surgically created incisions; however, their use in closing traumatic lacerations should not be overlooked. With the right indications, staple closure can be a time-saving and effective method of soft tissue trauma management. Staple closure is ideal for linear lacerations of the extremities, trunk, and scalp. Studies demonstrate that the cosmetic result is as good with staple closures as with traditional suture closure techniques. In a cost analysis study, suturing of a traumatic laceration was shown to be approximately three times more costly than stapling, with the cost differential increasing as the length of the laceration increased.²⁶ Other advantages of staple closure include rapidity, safety to the operator due to less risk of needle-stick injury, good cosmesis, resistance to infection, less wound inflammatory response, and they are well tolerated by patients. One disadvantage is that two people are required for an ideal staple closure technique. Other disadvantages to the use of staples include the need for a special removal device as well as discomfort upon removal.

Staple closure is indicated in wounds of the scalp where hemostasis has been achieved and the galea is not torn. It is also indicated in linear, sharp lacerations of the extremities or trunk but generally not used on the face. Staple closure can also aid in temporary closure of superficial lacerations or for rapid hemostasis when other life-threatening conditions take priority. Metal staples can produce artifact on computed tomography (CT) scans and can move during magnetic resonance images so their use is contraindicated if the need for those studies is anticipated.

Postoperative care

Postoperative wound care should include verbal and written instructions and information about the dressing management, cleansing of the wound, activity limitations, pain management, expectations of the appearance of the wound during the healing course, and follow-up appointment. Patients should be instructed to keep their dressing intact for the first day. On the second postoperative day, the dressing can be removed and the wound cleaned and dried. In a study of 200 head and neck lacerations and surgical incisions, investigators concluded that allowing patients to wash their wounds within as little as 8 hours after closure had no effect on healing or rate of infection.²⁷

Patients should be informed of the activity limitations that are necessary to prevent wound disruption. Pain management strategies should be discussed and patients should be given a realistic expectation of the amount of discomfort they may encounter, as well as the amount of relief they can expect from medication and other pain relief methods. The patient should understand the changes they can expect in the appearance of the wound, and along with the surgeon, develop realistic goals and expectations for the final appearance of the scar. Management of the scar and timing of possible revision should be discussed, with an endpoint clearly established. Written instructions and follow-up visit appointments should be given to the patient upon discharge.

Dressing management

Wound dressing choices depend on the type and location of the wound, as well as the operator preference. Repaired lacerations of the face can generally be left uncovered. Due to the high vascularity of facial skin, these wounds usually heal well and have a low risk of infection. Use of petrolatum-based topical antibiotic over sutured traumatic lacerations has been shown to reduce infection rate²⁸ and encourage epithelialization.²⁹ The use of white petrolatum ointment may be just as effective at preventing crusting around the wound encouraging epithelialization to occur rapidly and allowing easy removal of sutures with less risk of contact sensitivity than antibacterial ointments.³⁰ A thin layer of ointment over the sutured repair will prevent the unbandaged wound from desiccation and an ultimate delay in epithelialization. Occasionally, wounds in the maxillofacial region will require dressing for protection from contamination or for immobilization of the wound. Wound dressings for specific anatomic locations are discussed in the respective wound section.

Suture and staple removal

When non-absorbable sutures or staples are placed for wound repair, removal is necessary as part of the

wound aftercare. In the maxillofacial region, the timing for removal differs from that of the rest of the body and is in general much earlier. For the face or ear, sutures should be removed in 4–6 days, for the scalp 6–8 days, and for the neck 5–7 days. Sutures in the maxillofacial region should be removed as early as possible; however, at this time, the skin has only regained about 5–10% of its tensile strength. Thus, any stress on the skin after suture removal will lead to dehiscence. It is necessary to continue to support the skin while healing continues and this can be accomplished with adhesive tapes, with or without the use of adhesives. The tapes should be allowed to slowly peel off over several days following placement, as the patient repeatedly washes the area.

Suture marks are complications of laceration repair and their development depends on several factors. The tension with which the suture knot was tied can be a cause. Excessive tension on the tissue leads to small areas of local ischemia and the appearance of unsightly suture marks after healing has taken place. The type of skin repaired is also a contributing factor. The skin of the eyelids is unlikely to reveal suture marks; however, other areas such as the lower third of the nose and the nasolabial areas are vulnerable to marks. Skin variation among patients also plays a role in the formation of suture marks. People who form keloids have a greater risk of having suture marks after laceration repair. The development of a suture abscess also lends itself to the development of suture mark formation. Braided sutures and silk are more likely to invoke an inflammatory reaction at the site of the suture and cause stitch abscesses and therefore more likely than nylon or staples to leave marks. Finally, the duration of the suture or staple left in place determines the formation of suture marks. Staples are kept in place the same period of time as sutures would be for that particular anatomic location. After 14 days in place, the suture track has become epithelialized and marks will be inevitable after suture removal. If the suture is removed before 7 days, no suture marks will be evident. The period between 7 and 14 days is a gray zone for the retention of suture marks that persist once the sutures or staples are removed.

Healing adjuncts

Vacuum-assisted closure

While negative pressure dressings have been used by surgeons for promotion of healing of chronic extremity wounds, infected sternotomy wounds, open abdominal wounds, and decubitus ulcers, little use in the maxillofacial region has been described. Vacuum-assisted closure (VAC) devices (Kinetic Concepts Inc., San Antonio, TX) combine occlusive dressings with negative pressure to improve blood circulation in wounds and thus speed healing. Studies to determine mode of action for this process have shown that

negative pressure applied to wounds increases capillary blood flow velocity, increases the caliber of capillaries, stimulates endothelial proliferation and angiogenesis, and restores continuity of the basement membrane by narrowing endothelial spaces.^{31,32} The restored basement membrane decreases the permeability of blood vessels, thus decreasing wound edema. This altered wound physiology results in faster production of granulation tissue and allows for less frequent dressing changes. Its effect on increased bacterial clearance of the wound is controversial.³³ VAC devices are also used as bolsters for split-thickness skin grafts to create uniform pressure over the graft and therefore enhance graft success.

Despite its paucity in the literature, VAC has utility in the head and neck region (Fig. 44.1). When using VAC systems, it is necessary to obtain an airtight seal over the wound. Maxillofacial wounds, with their extreme contours and hair-bearing skin, make the creation of an adequate seal difficult. Situations that preclude the use of VAC are presence of malignancy or eschar tissue in a wound, presence of exposed dura, and presence of a fistula to an organ or cavity. Its use in the presence of osteomyelitis is debatable.

Leech therapy

A common occurrence in partially avulsive soft tissue injury is the disruption of the delicate vascular supply. Injury to veins with maintenance of arteries may result in an imbalance of arterial inflow and venous outflow causing blood stasis within the tissue. This congestion leads to hypoxia of the tissue, thus compromising its viability and setting the stage for an endpoint of necrosis. When surgical repair of the venous system is not possible, medicinal leeches (*Hirudo medicinalis*) may be used to relieve congestion.^{31,35}

Medicinal leeches have been used for centuries to salvage skin grafts and tissue flaps whose viability is threatened by the obstruction of venous outflow.^{34,35} In addition to actively drawing off blood for use as a bloodmeal, the leech injects an anticoagulant contained within its saliva, hirudin, which allows continued bleeding from the site even after the leech is removed.³⁶ Hyaluronidase and antihistamines are also released by the leech causing diffusion of the hirudin into the wound and causing vasodilatation to prolong bleeding at the site.³⁶

Complications of leech therapy include significant blood loss, allergic reaction to the leeches' salivary proteins, scarring, migration of the leech, and psychological distress of the patient.³⁵ Leech-associated infections are also a recognized complication of leech therapy. Leeches contain multiple bacterial flora within their guts, with *Aeromonas* being the predominant genus. Antibiotic prophylaxis with a quinolone or aminoglycoside is necessary throughout the course of leech therapy.³⁶ Care must be taken during site

Fig. 44.1 (a) A female involved in a motor vehicle accident presents with an infected neck wound 5 days after surgical intervention. After debridement, a wound VAC is used to create a granulation tissue bed prior to coverage of the wound with a split-thickness skin graft. (b, c) A polyurethane sponge is cut to the size and shape of the wound and secured into the wound with an occlusive dressing. (d, e) A small opening is created in the occlusive dressing and airtight tubing is connected to the vacuum pump. (f) Continuous negative pressure of 100 mmHg is applied to the sponge and maintained continuously. (g) The wound VAC sponges are changed every other day for a total of 8 days of therapy. (h) The result is a healthy bed of granulation tissue.

preparation to avoid alcohol-based skin cleaning products which may agitate the leech, causing it to regurgitate and potentially infect the site with its own bacterial flora.

Effective arterial perfusion is confirmed by tissue puncture with resultant brisk bleeding. If upon pinprick, the segment has little or no bleeding, the arterial supply, in addition to the venous supply, is compromised and this tissue will most likely not be salvageable. Once true venous congestion is diagnosed, the patient's skin should be cleaned with soap and rinsed thoroughly with water. The head of the leech is guided to the area of maximum congestion until attachment occurs (Fig. 44.2). Once a leech attaches, it will stay in place for about 30 minutes or until it becomes full and falls off. Adequate venous outflow can be produced by adjusting the number of leeches applied. Some type of barrier such as gauze or an Op-Site dressing should be used to prevent migration of the leech (Fig. 44.3). Once the leech detaches, it should be discarded as a biohazard after one use.³⁵ Local clots formed at the bite wounds should be gently removed. While the average 5 ml of bloodmeal removed during feeding may initially help to decongest the tissue, the real rationale behind the use of leeches is to create a puncture wound that bleeds for hours.^{35,36} The bite wound can ooze for up to 10 hours, losing up to 150 ml of blood. Leeches are generally applied to congested tissue for about 3–5 days until new vessel ingrowth develops to adequately sustain venous drainage. Postoperative care of the patient includes

wound inspection for signs of infection and daily hemoglobin checks.

Considerations for the extremes of age

Advanced age is a risk factor for detrimental wound healing. While the mechanism of age-related delay in wound healing is not entirely understood, it is multifactorial in nature and is the subject of a substantial body of research. With the rate of growth of the elderly population in the US exceeding any other segment of the population, it is clear that this group of patients will benefit from the growing interest in research of the physiologic effect of aging on wound healing and methods to promote healing in the aged.

Concomitant disease in the elderly is one factor contributing to delayed wound healing. Diabetes, cardiovascular disease, renal disease, malnutrition, and obesity are among the age-related diseases that contribute to ischemia in traumatized tissues, thus compromising healing. However, research also suggests that the aging repair process is affected at the cellular level.

Skin becomes weaker with age due to the loss of collagen and elastic fibers, and decreased moisture content. A decrease in macrophages results in decreased skin immunity and a decrease in melanocytes results in decreased protection from sunlight. By the eighth decade, epidermal turnover is decreased by 50%.³⁷ With a loss of subcutaneous fat, a loss of

Fig. 44.3 (a) Partial ear avulsion results in a compromised venous outflow while arterial supply is maintained within the small pedicle. (b) The partially avulsed ear is repaired with primary closure and true venous congestion is diagnosed. (c) Leeches are placed at the area of maximum congestion for 5 days. (d) Barriers should be used to prevent migration. (e) The ear has good esthetics after 4 weeks.

elasticity, and a relative desiccation of the skin, the elderly are at greater risk of tearing and bruising.

Specific wounds

Abrasion

Abrasive injuries are among the most common injuries in many age groups. Although the general public often dismisses such injuries, abrasions may become serious and should be thoroughly evaluated.

Abrasions are typically characterized as superficial injuries that denude the surface epithelium; however, involvement of deeper cutaneous layers must be ruled out. The large surface areas that these types of injuries produce serve as massive portals of entry for microbes, much like burn injuries. Without the epithelial surface barrier intact, proper management is required to prevent poor outcomes such as infection, scarring, or contamination tattooing.

Abrasive wounds, generally produced by shearing contact with rough surfaces such as roadways or concrete, often present with the impaction of foreign bodies or other environmental relics. Abrasions require thorough lavage with irrigant along with careful inspection and removal of any solid remnants and necrotic epithelium. Remaining irritants may be the source of prolonged inflammation, infection, and eventual discoloration of the wound following heal-

ing. Abrasions are generally more painful than lacerations or puncture wounds and more aggressive forms of pain management should be considered.

Abrasive wounds should be dressed with antibiotic ointment and covered with sterile gauze if necessary to maintain wound moisture until re-epithelialization is complete and final resolution of the wound takes place. Some practitioners elect to discontinue antibiotic ointments after a 72-hour period, dressing the wound with petroleum jelly or Vaseline for the remainder of healing time. Abrasive wounds are commonplace and often go untreated, yet because of the possible deleterious effects of contamination, these superficial wounds require management.

Laceration

Some basic principles apply when considering closure of simple lacerations of the skin. It is important that the layers of the laceration be reapproximated to their appropriate counterpart. That is, dermis should be sutured to dermis. Lacerations should be closed in layers with resorbable sutures used for deep closure of the dermis to reduce tension on the skin edges. Minimizing wound tension prevents necrosis which will ultimately delay healing and cause a cosmetically unacceptable result. Skin should be closed with appropriately sized non-resorbable suture such as 5/0 and 6/0 nylon. Scars contract with time, so

wound-edge eversion is an important principle. Vertical and horizontal mattress suture techniques as well as introducing the suture needle at a 90° angle to the tissue during percutaneous closure help evert wound edges. A technique that slightly raises the wound edges above the skin plane will ultimately result in a cosmetically acceptable closure.

Stellate lacerations result from blunt trauma and are less likely to yield a cosmetic result even when meticulously closed. Often, the edges of the lacerated tissue are contused and beveled, making primary repair difficult. These wounds should not be excessively debrided, which may be the tendency due to the poor appearance of the edges. Judicious debridement should be employed so that tissue removal will not compromise a later revision or reconstructive effort.

Through-and-through lacerations involving the oral cavity are complex lacerations necessitating layered closure (Fig. 44.4). After thorough debridement and cleaning, repair begins with alignment of the vermillion border and white roll if involved. These landmarks can be tacked with nylon sutures which can be replaced after muscular and mucosal repairs. Next, the muscle is closed with deep 5/0 absorbable sutures followed by mucosal closure with 4/0 or 5/0 absorbable suture. The skin is then closed with 5/0 and 6/0 nylon interrupted sutures. Even after good approximation of the layers, mucosal scarring can occur which can limit function (Fig. 44.5). Scar exci-

Fig. 44.4 (a, b) A young female patient sustained a complex through-and-through laceration of the chin necessitating a multilayered closure.

sion can help to release the fibrous banding. For skin lacerations, dermabrasion can help improve the look of a cosmetically unacceptable scar (Fig. 44.6).

Hematoma

Blunt trauma and contusion to the soft tissues of the head and neck result in hematoma formation, or a self-limiting bleeding within the subcutaneous tissue from minor vessel disruption. Usually, hematomas resorb spontaneously; however, some may become encapsulated and require evacuation. In early hematoma formation, aspiration with a 14 or 16 gauge needle will usually solve the problem. If the hematoma has matured such that the coagulum is in the jelly stage, incision with removal of the clots is necessary.

Fig. 44.5 Mucosal scarring can result in limitation of opening and lower lip movement.

Fig. 44.6 (a, b) The cutaneous scar can be improved with dermabrasion.

Pressure dressings, drain placement, and meticulous control of bleeding at the time of repair help to prevent hematoma formation.

One area where hematoma formation is particularly detrimental is the auricle. If left untreated, fibrous organization of the clot may take place resulting in “cauliflower ear”. Complete evacuation of the blood and placement of molded pressure dressings which compress the anterior and posterior perichondriums toward each other will minimize the likelihood of recurrence.

Avulsion

When small areas of tissue are lost due to trauma, undermining the adjacent skin will allow the margins to be directly approximated and closed. Larger defects, however, will require skin grafts or flaps for coverage. Direct approximation should be used with caution in areas proximal to certain anatomic features such as the eyelid, eyebrow, lip commissure, or nasal ala. These areas can become distorted if their surrounding tissue is undermined. Full-thickness defects greater than 2cm² are considered to be large defects and may need to be covered with grafts or flaps.³⁸

Mucosa

In general, lacerations, abrasions, and burns of the mucosa heal quickly with little intervention needed; however, if large or gaping, intraoral wounds benefit from approximation and suture closure. For closure of mucosal violations, 4/0 or 5/0 interrupted chromic gut suture will suffice. Failure to repair lacerated mucosa can result in scarring with functional compromise. Contaminated wounds or bite wounds should be debrided, cleaned, and closed loosely with sutures. Patients must maintain good oral hygiene throughout healing and continue with a soft diet until the mucosa is healed.

Tongue

The tongue often receives a portion of the injury secondary to trauma to the orofacial region due to its position and motility. Injury to the tongue ranges from non-operative superficial lacerations to complete avulsion. The tongue is a highly muscular and highly vascular tissue which generally lends itself to speedy recovery times and a high potential for repair. However, this highly vascularized tissue also lends itself to risk of hematoma formation or massive edema that can lead to upper airway obstruction within a short time period after injury or after repair.

Somewhat unique to the tongue, is the fact that many injuries may be self-inflicted. Characteristics of the laceration from a self-inflicted bite may also help in diagnosing a patient whose tongue laceration is secondary to an episodic neurologic disorder. Presentation of the injury may help distinguish

between syncope, stroke, and seizure disorder. Patients whose cause for loss of consciousness is psychogenic, typically do not incur tongue injury; however, when biting does occur in this situation, it is usually the tip that is injured.³⁹ Patients with blackouts due to hypoglycemia or transient ischemic attack are most likely to lose consciousness gradually and therefore uncommonly sustain a tongue laceration. Tongue biting, however, is highly specific for generalized tonic-clonic seizures and usually results in lateral tongue lacerations.⁴⁰

In some age groups, piercing and placement of a solid bar through the dorsal and ventral tongue are considered fashionable. Although the topic is still being debated in the literature in terms of traumatic potential to the dentition, it must be recognized that the site itself is a portal of entry for infection. In a study by Krause *et al.*, 15.4% of patients who had undergone tongue piercing had to seek medical treatment for a complication.⁴¹ Complications such as local infection, deep tongue abscess with subsequent Ludwig’s angina, hemorrhage leading to hypovolemia, and endocarditis have all been reported in the literature.

The largest and most common category of traumatic injury to the tongue falls under laceration. Statistically, children outnumber all other age groups and demographics in number of tongue lacerations. Although most lacerations of the tongue are considered superficial and require no treatment, the depth of the wound can vary and thus mandate different management modalities. These superficial lacerations heal quickly by secondary intention, and should simply be irrigated to remove any foreign bodies potentially involved. Literature suggests that suturing small non-gaping tongue lacerations (less than 1 cm in length) in young children does not affect the quality of the outcome; however, little has been written on the subject.⁴² Often it is the patient’s dentition that pierces the surface of the tongue secondary to strong impact from the inferior of the mandible or from a sympathetic reaction leading to activation of the muscles of mastication without regard for the position of the tongue. Lingual abscesses have been noted following biting of the tongue; however, they generally follow deeper penetrating wounds. Deeper injury into the muscle layers of the tongue requires careful examination of vascular integrity, as well as for the presence of foreign bodies. While tooth fragments are more often found within lip lacerations, there are reports of teeth becoming embedded into the body of the tongue during trauma.^{43,44}

These wounds should again be aggressively irrigated like all other traumatic lacerations, and approximation of the muscle layers with chromic suture should be achieved. Superficial sutures may then be placed to achieve healing by primary intention. Careful inspection of the vasculature is of primary importance to assess any injury to the lingual artery. Finally, prior to closure, all bleeding must be con-

trolled to minimize the chances of hematoma formation.

Hematoma formation in the tongue can be considered an emergency secondary to airway compromise and can lead to death. Hematomas that may result postoperatively from laceration closure most commonly occur in patients with generalized seizure disorders but also have been reported in anticoagulated patients postintubation. The patient can commonly appreciate any swelling around the base of the tongue and airway constriction will often create labored breathing, dyspnea, or wheezing. Ecchymosis is generally evident. Once the airway is secured, aggressive treatment to drain the hematoma and seal the source of the bleed is often initiated. Those areas near the base of the tongue can be especially problematic for the surgeon in terms of access and visualization. Electrocautery or ligature of the vessel is often employed to secure the bleed. Hirudotherapy may also provide benefit to treating venous congestion in the hematoma site; however compliance may be an issue (Fig. 44.7). The literature indicates that cases of macroglossia extending beyond the dentition or alveolar ridges may be managed with high success with leech therapy.⁴⁵ Appreciable resolution may be noticed within the first 6–8 hours and complete resolution often within 24–36 hours. Other treatments of traumatic macroglossia include positive pressure, steroid therapy, and manual reduction of the tongue back into the oral cavity; however each delivers questionable results.

Tongue avulsions or complete amputation are not rare in more serious traumatic injuries. Control of bleeding and placement of sutures through both the muscular and superficial layers may successfully treat some partial avulsions when vasculature was not compromised. However, in the case of complete

avulsion, immediate microsurgical revascularization of the amputated tongue may be the only opportunity for salvage. The literature indicates three successful cases in which near complete transection of the tongue was successfully treated by revascularization.^{46,47,48} The best results should be anticipated if revascularization occurs within the 8-hour threshold commonly accepted for revascularization of muscular tissue. However, one of the three successful cases in the literature chronicled a 16-hour ischemic period before microvascular anastomosis of the lingual artery and vein was completed.

If microscopic revascularization fails or is not attempted for complete amputation of the tongue, successful salvage is rare. And while the tongue plays a critical role in swallowing, speech, and airway protection, some patients are able to maintain a good quality of life and perceive the injury's impact on articulation as minimal should the avulsed segment be lost (Fig. 44.8).

In the more serious cases of severe traumatic injury, it must be appreciated that the patient may have sustained other injuries. A patient should be stabilized prior to any treatment from the surgical specialist. Often the patient may have sustained neurological trauma or be temporarily comatose, and prevention of trauma to the soft tissues of the tongue is the goal. Hanson and Wood lay out methods for fabricating tongue splints that will aid in the prevention of unconscious trauma while the patient is incapacitated.^{49,50}

Traumatic injury to the tongue is often benign and limited to children; however, serious airway consequences may develop in more extreme cases. Control of bleeding and aggressive irrigation prior to closing wounds will generally lead to healthy repair. Postoperative examination of more significant injury

Fig. 44.7 (a) A patient sustained trauma to the tongue with resultant hematoma and significant venous congestion. (b) Leeches can be used to relieve the venous congestion and restore vascular integrity to the tongue.

Fig. 44.8 (a) This patient is a 50-year-old male who presents alleging that his brother had bitten off a portion of his tongue during an argument. (b) The amputated segment measured 4.5×3.5 cm. (c) The avulsed segment was repaired; however, no microvascular replantation was performed. (d) The distal tongue became necrotic and needed removal leaving the remaining wound to repair secondarily. The patient refused revision of the wound edges and primary closure of the remaining stump and went on to heal uneventfully. (e) Sixty days post-injury, the patient denies a large negative impact in his quality of life.

should always include examination of lingual nerve function and taste sensation.

Nose

Due to the protrusive position of the nose from the midface, many cases of facial trauma include a nasal component. The nose is a complex structure with an array of tissue components that are dynamic during growth and eventually become central to adult facial esthetics. Nasal trauma may present in combination with other facial injury; however, many affect the nose alone. Knowledge of the nasal anatomy in combination with a basic understanding of the biome-

chanics of the injurious impact is of paramount importance when planning treatment of nasal trauma. Thorough evaluation, diagnosis, and treatment planning of soft tissue injuries to the nose will provide the most acceptable prognosis for repair.

Evaluation of nasal trauma can be a complex task. With the amount of edema associated with nasal or other facial trauma, palpation and visualization may have minimal value if delayed. Ecchymosis is often present around the orbits and significant edema is generally appreciated. Traumatic telecanthis or crepitus around the upper eyelid should always be further investigated to rule out naso-orbital-ethmoid (NOE) fracture or medial wall fracture. An accurate evalua-

tion is generally best obtained immediately upon admission, including CT scan, airway assessment, rhinoscopy, and, most importantly, comprehensive digital palpation.

Evaluation is often divided into three nasal compartments: upper, middle, and lower.⁵¹ These anatomic compartments will aid the surgeon in establishing breadth of injury and extent of surgical repair. Because the nose as a unit consists of bone, cartilage, and skin so tightly connected, a discussion of soft tissue trauma to the nose must include all of the components. Positive upper vault compression evidenced by digital palpation indicates nasal bone fracture and often disunion from the frontal bone. A positive result is evidenced by collapse at sellion and apparent “disappearance” of the nose into the ethmoid sinuses.⁵¹ Upper compartment injury most often indicates need for manual reduction often in combination with bony fixation. Positive middle vault compression results in nasal tip deflection superiorly, as the injured septum gives way below the bony-cartilaginous junction. Pressure applied at columella or the nasal tip resulting in collapse or hyper-rotation indicates injury to the lower vault. This method of classification is consistent with the Brown-Gruss system. The age of the patient will also impact delivery of care, especially when bony or cartilaginous involvement is appreciated. Facial growth centers such as the septo-vomerine suture may be impacted and more serious esthetic sequelae could be expected as the child reaches nasal

maturity at 18–20 years in males and 16–18 years in females. Importantly, disruption of the external branch of the anterior ethmoidal artery is more common in children due to the lack of osseous protection afforded in the mature skeleton; this problem is generally absent in adult populations. Control of hemorrhage, especially in children, with nasal packing is always advisable to prevent hematoma formation. Frequent examination of the septum is critical because septal hematoma is significant and a potentially devastating sequela of nasal trauma. Untreated, this can lead to infection, necrosis, and resorption of septal cartilage. If large enough, septal collapse occurs resulting in saddle-nose deformity. Meticulous evaluation and diagnosis of nasal injury will lead to more predictable repairs.

Soft tissue injuries to the nose are often comprised of skin flaps, cartilage tears, mucosal violations, or a combination. A three-layer closure is necessary to repair full-thickness lacerations. Due to the complex anatomy of the nose and variation in vectors of impact, these flaps are often irregular in shape which may prove challenging to the surgeon. Thorough assessment of the viability of the flaps is often the most critical and unfortunately the least sophisticated and predictable objective. Capillary refill, color, and bleeding are three clinical indicators used to predict viability; however, no one finding should be trusted individually. A bluish, congested flap with thinned borders will often breed a questionable to poor prog-

Fig. 44.9 (a) A young patient sustained a partial avulsion of his nasal tip which appears dusky. (b) The small pedicle is apparent after closure of the flap. (c) The patient presents after healing. Some flaps with questionable viability may go on to succeed.

nosis, while more viable flaps will tend to be pink and free of ischemic elements. As discussed elsewhere in this chapter, hirudism (use of leeches) is a viable treatment for more severe flap injuries with signs of moderate to severe venous congestion. It must be remembered that even the most clinically viable appearing flaps may often be lost, and conversely the most questionable may succeed (Fig. 44.9). Avulsive injuries may be treated with regional flaps for primary repair. More progressive therapies including island composite nasal flaps, prefabricated porous alloplastic materials, and free autogenous grafts are often considered when flaps are lost and secondary repair becomes the goal. Avulsive injuries may also be left open, allowed to heal and reconstructed at a later time.

Gentle but thorough irrigation of the wound along with removal of any foreign elements should be undertaken. Failure to do so may lead to infection and jeopardize the surgical repair. Closure of any nasal wound should be directed towards healing by primary intention, along with emphasis on esthetics and function. Repair should start at the ala if involved, maintaining it in proper position. When repair begins cranially and progresses caudally, there is a tendency for the alar rim to be displaced superiorly, leading to an unesthetic result. Deeper lacerations should be closed in individual layers, using fine absorbable sutures for mucosa, and absorbable sutures to approximate separated cartilage, perichondrium, and muscle layers. Failure to reapproximate important muscle layers, including any involved muscles of facial expression, will have severe implications on the patient's esthetic outcome. Furthermore, the cartilaginous components provide the nasal tip with its major support. This support is derived from the size, shape, and resilience of the medial and lateral crura, the attachment of the medial crus to the septal cartilage, and the attachment of the upper and lower lateral cartilages.⁵² Careful attention should be paid to these areas when reconstructing the nose to provide the most esthetic result. Often, more severe trauma will necessitate reapproximation of cartilage to the bone underlying the superficial rhinion, the point where the nasal bone and upper lateral cartilages meet. Functional impairment may result, with nasal passage stenosis, if the upper lateral cartilages are not positioned properly in relationship to the cartilaginous septum. The surgeon must keep both functional and esthetic implications in mind when treating these cases. Intranasal stenting after mucosal repair may help prevent or minimize the development of stenosis or synechiae. Final flap closure should approximate clean healthy borders with fine nylon suture for a better result. More severe injuries may necessitate multiple surgeries, however most superficial injuries may be treated in the clinical environment with local anesthetic. Steri-strips (3M Healthcare, St. Paul, MN), antibiotic ointment, in combination with other protective dressings, are all encouraged.

After treatment, postoperative instructions should be given, steroid or anti-inflammatory medications are often prescribed, and the patient should be followed closely to ensure proper healing. The patient should be evaluated at regular intervals to assess any sensory deficit including anosia or dysgeusia. Any evidence of hematoma formation must be immediately addressed. Hematoma formation is most often diagnosed via anterior rhinoscopy as a bulging of the lateral nasal wall between the caudal edge of the upper lateral nasal cartilage and the cephalic margin of the alar cartilage. Muscles of facial expression should be tested and appropriate sinus drainage should be verified. Nasal injuries are among the most common facial injuries and also are often difficult to treat. Careful closure with the appropriate materials in conjunction with realistic patient expectations will result in the most successful cases.

Ear

Traumatic auricular injuries consist of lacerations ranging from simple to full thickness, avulsions or partial avulsions, and hematomas. The auricle consists only of skin, a small amount of subcutaneous tissue, and cartilage. The key to repairing lacerations on the external ear is maintenance of the cartilaginous framework. If simple, the laceration can be repaired with interrupted non-absorbable sutures such as 5/0 nylon to approximate the skin. If cartilage is disrupted, a minimal number of fine, absorbable intercartilaginous sutures should be placed. This is followed by closure of both skin surfaces and placement of a molded pressure dressing. With avulsions or partial avulsions, even small segments will usually survive due to the abundant blood supply. The first landmark for replacement of the partially avulsed ear is the external auditory canal. Failure to appropriately realign the canal can lead to stenosis – a complication which is difficult to correct later. The cartilage should be sutured in a clockwise fashion around the canal followed by approximation of the helical rim. Once these landmarks have been established and sutured, the remaining cartilage and skin can be closed.

Blunt injury to the ear can cause a hematoma which requires immediate drainage and application of pressure dressing in order to prevent clot organization and fibrous distortion of the auricle, or “cauliflower ear”. If needle aspiration of the hematoma is unsuccessful, a small incision should be made through which to evacuate the blood clots. Recurrence is likely unless pressure is applied from either mattress sutures or a molded pressure dressing which can also be sutured into place (Fig. 44.10).

Complete avulsions of the ear may be treated by either replantation or implantation. Replantation can be considered if the repair occurs soon after injury, if the injury is clean, and there is little damage to the avulsed segment. Once the replantation is performed and vascularity is re-established, it is important to

Fig. 44.10 Pressure is applied to the repaired helix from a pressure dressing held in place with mattress sutures that compress the perichondria to prevent hematoma development.

deal with the resultant venous congestion. This may be done by making multiple skin incisions in the congested area or using leech therapy. Mladick *et al.*⁵³ described a technique which they called the “Pocket Principle” for implantation of the avulsed ear. The avulsed ear is dermabraded and then reattached. The dermabraded reattached ear is then buried into a retroauricular subcutaneous pocket for 3–4 weeks where revascularization and epithelialization occur. The auricle is then bluntly dissected from the pocket and externalized. Many modifications of this technique have been described to overcome problems such as poor vascularization or poor soft tissue coverage upon externalization of the avulsed ear.

Eyelid injury

Traumatic injuries to the eyelids often present in combination with other periorbital injury including, but not limited to, fracture of the orbital rims and medial or lateral wall fractures. Soft tissue injuries involving the periorbital area are of high importance due to the esthetic and functional consequences of disrepair. Injuries to the eyelid may range from simple surface lacerations to complex globe injuries involving muscles for retraction of the eyelid, suspensory ligaments, tarsal plates, and conjunctiva. The implications of improper repair or misdiagnosis of injuries to these structures may lead to esthetic disturbance and loss of symmetry as well as significant dysfunction.

Evaluation is the critical step for injuries involving the periorbital structures. Evaluation should include examination of visual acuity, extraocular muscle mobility, V2 sensory evaluation, as well as mechanical palpation. Consultation with an ophthalmologist is often indicated. The layers of the eyelids incorporate many tissue components that are often difficult to visualize without high-powered magnification. Due to limitations in the acute setting of injury, loupe

magnification is often the preferred method of evaluation of fine structures. Knowledge of the periorbital anatomy is of paramount importance when determining extent of injury and during repair. Evaluation of deep laceration injury necessitates examination of each layer of the eyelid from skin, orbicularis oculi, retractor muscles, ligaments, tarsal plates, and conjunctiva. Each layer will have consequences on outcome and involvement of specific complex structures may impact the final prognosis.

Injuries to the upper eyelids are generally more complex and more difficult to repair than lower eyelid injuries.^{54,55} The upper eyelids are anatomically complex and serve to protect the globe from injury. Upper eyelid injuries can involve the lacrimal gland or drainage apparatus and, with improper repair, lead to epiphora. The lacrimal gland is an almond-shaped gland which is housed in the lacrimal fossa adjacent to the superior and lateral rectus muscles. It is divided into a palpebral and deeper smaller orbital lobe by the aponeurosis of the levator palpebrae superioris. During wound exploration of the upper eyelid, attention must be given to determine lacrimal gland involvement. The more pink, vascular, and firm quality of the lacrimal gland will allow its differentiation from orbital fat. Care must be taken to ensure its reposition into the lacrimal fossa during avulsion or severe laceration in order to restore continuity and function (Fig. 44.11).

Injury to the upper eyelid retractors has serious esthetic and functional repercussions. Levator palpebrae superioris, the levator aponeurosis, and Muller's muscle all act as eyelid retractors for the upper eyelid. Injury to these muscles must be included in the primary repair or eyelid ptosis is often the result. Reattachment of Whitnall's and Lockwood's suspensory ligaments will also minimize globe ptosis. Laceration of the medial palpebral ligament causes the lid to displace laterally. Furthermore, approximation of the conjunctival layer is beneficial to prevent complications including symblepharon and eyelid retraction.⁵⁴

Simple surface lacerations involving the eyelids are often of little consequence. The eyelids employ a thin skin layer with high regenerative capacity that most often leads to quick and esthetic resolution with proper closure.⁵⁴ Fine suture such as 6/0 nylon should be employed to close these surface lacerations. If non-compliance with removal is anticipated due to a patient's age, rapid absorbing sutures can be placed. Studies reveal no difference in cosmetic outcomes in facial lacerations closed with absorbable sutures compared to nylon.^{18,19,56}

Lower eyelid injuries are often less complex anatomically and produce less significant complications in repair. However, the lower eyelid can be the site of very complex injuries which may include different degrees of tissue loss necessitating flap advancement or donor tissue to achieve primary closure (Fig. 44.12).

Fig. 44.11 (a) A child presents with a deep laceration of the upper eyelid. (b) Wound exploration reveals avulsion of the lacrimal gland from the fossa. (c, d) The lacrimal gland is reimplanted back into the lacrimal fossa and secured with absorbable suture. (e) Layered closure of the eyelid laceration ensures both an esthetic and a functional result, as demonstrated by the ability to produce tears.

Donor tissue is most often taken from the contralateral eyelid, but has also been harvested from supraclavicular and periauricular areas.^{54,55,57} Full-thickness injuries should be closed in layers, with particular attention paid to the tarsal plate and levator aponeurosis reapproximation. Eyelid margin involvement necessitates marginal reapproximation using fine chromic suture to prevent eyelid notching.⁵⁴ Lacerations involving the medial canthus may present with traumatic telecanthis, medial canthal blunting, and epiphora, and often signify complex injury.⁵⁴ Traumatic telecanthis is often a sign of NOE fracture or medial wall fracture, and is usually defined as any measurement greater than 33mm. Reattachment of the medial canthal tendon will alleviate pressure on the lacrimal apparatus and help avoid chronic epiphora.⁵⁴ Complex eyelid reconstruction often yields poor functional results and revision is almost always necessary.^{55,57}

Eyelid injuries may be very complex. Thorough assessment will allow determination of all of the structures damaged and in need of repair. The upper and lower eyelids house the tear drainage system which may be involved in complex lacerations. The canaliculi and the lacrimal apparatus are at risk of injury when trauma to the eyelids occurs (Fig. 44.13). Thorough evaluation at the time of injury may prevent long-term complications from an undiagnosed injury. The prognosis often depends on the location and depth of injury, associated structures involved, and availability of tissue for repair.

Canaliculi and lacrimal apparatus

Disruption of the nasolacrimal apparatus can occur from shearing forces to the midface which have also involved the bony skeleton. Dysfunction of tear flow can also be caused by a purely soft tissue injury

Fig. 44.12 (a, b) A male patient presents with a soft tissue avulsion of the lower eyelid. (c–g) Adjacent tissue was rotated to provide coverage of exposed conjunctiva and create a new lower lid.

involving laceration of the canaliculi. The nasolacrimal apparatus begins as the eyelid puncta drain to the medial canthus, and continues as the canaliculi, the common canaliculus, the lacrimal sac, and finally the nasolacrimal duct. The nasolacrimal duct courses from inferior to the middle canthus through the nasolacrimal canal to its opening in the inferior nasal meatus. Injury may occur at any point along the

apparatus, most commonly in combination with LeFort II and LeFort III fractures or with penetrating injuries.⁵⁸ NOE fractures also show high association with injury to the lacrimal apparatus, particularly with dacryostenosis in the months following injury.⁵⁸ These injuries may be highlighted on CT scan, or through digital subtraction macrodacryocystography, which incorporates a radioactive dye through

Fig. 44.13 (a) A motor vehicle accident is the cause of these facial lacerations including a laceration of the medial aspect of the upper and lower eyelids. (b, c) Thorough evaluation of the wound reveals lacerated superior and inferior canaliculi which were intubated using a Crawford tube and dacryocystorhinostomy was performed to prevent chronic epiphora.

the nasolacrimal apparatus. Although injury to the lacrimal apparatus is relatively rare in most midfacial trauma, thorough assessment can minimize the likelihood of the chronic complications involved in lacrimal injury.

Any injury to the orbit, especially the medial orbit and bridge of the nose, should increase suspicion of an injury to the lacrimal apparatus. As noted previously, symptoms may present acutely, but most commonly present months following midfacial injury. The most common symptom is epiphora, while others include visual impairment, midfacial anatomical distortion, nasal ecchymosis, and palpable step deformities involving the inferomedial orbital rim.⁵⁹ Although epiphora is the most common symptom involving traumatic injury to the lacrimal apparatus, it is most often appreciated as a chronic and persistent complication following midfacial injury. Further, the most common diagnoses related to symptoms of epiphora are inflammation/infection, obstruction, and tumor, which may further complicate diagnosis in minor injuries.⁵⁹ However, any patient presenting with epiphora should be questioned regarding any past trauma involving the associated structures.

Dacryocystorhinostomy is the standard treatment for diagnosed injury to the nasolacrimal apparatus. Many techniques exist, yet most center around the placement of silicone intubation systems or Crawford tubes while the system re-epithelializes and heals (Fig. 44.14).^{59,60}

This treatment has become well accepted; however, the current debate centers on prophylactic intubation of the system in all midfacial injuries. Traditional

management has emphasized correct fixation and wide open reduction of the fracture segments surrounding the pathway, to ensure osseous patency for the duct.⁵⁹ After proper fracture management, the lacrimal system may be addressed during a second surgery at 6 months postoperatively for those who present with symptoms. If segments surrounding the duct are allowed to heal out of anatomical position the duct could be obliterated, leading to long-term complications. Furthermore, many believe that achieving early and accurate repositioning helps avoid compression of the upper lacrimal pathways and some degree of telecanthis, which may result in decreased need for secondary surgery.⁷ More aggressive management has been predicated upon the high percentages of lacrimal complications associated with certain injuries. Studies cite figures that 20–47% of patients with NOE fractures experience nasolacrimal obstruction following their primary surgery.^{59,61} Spinelli *et al.* concluded that the addition of lacrimal intubation to the complex primary repair of selected midfacial injuries may indeed obviate the need for secondary lacrimal bypass surgery resulting from late cicatricial obstruction of the nasolacrimal duct.⁵⁹ Thorough irrigation and dye testing following intubation will ensure proper positioning and patency, regardless of when the procedure is performed.

Injuries to the lacrimal apparatus may result in serious long-term consequences in the form of persistent obstruction and recurrent epiphoral episodes if not treated. Prophylactic intubation of the nasolacrimal duct in patients experiencing fractures to high-risk areas, should be considered.⁵⁹ Patients with

Fig. 44.14 (a, b) This extensive forehead laceration involves the medial canthus of the right eye. The lacrimal duct is disrupted. (c–f) This skull is used to show the course of the nasolacrimal duct and the course of the dacryocystorhinostomy. (g) A shepherd's hook is illustrated. (h) It is used to grasp the silver solder tips of the Crawford tube. (i) A Crawford tube is silastic tubing with stainless steel stents on either end. (j, k) They are passed through the upper and lower canaliculi and through the opening created in the frontal process of the maxilla. The stents are recovered through the nose. (l) The metal stents are cut from the tubing and the ends of the silastic tubing tied together and secured to the nasal septum with a non-absorbable suture. The tubing is removed 3–4 months after surgery.

injury to the nasolacrimal apparatus should be followed closely for signs and symptoms associated with the injury at 1 week, 2 weeks, 1 month, 6 months, and 1 year.

Parotid duct and capsule

While parotid gland and duct injuries are rare, recognition of their occurrence in facial soft tissue trauma is critical. The complications of missed parotid capsule or duct injury are difficult to resolve. Standard

treatment protocols for these complications are controversial and have varying degrees of success.

The primary cause of parotid duct injury is from penetrating trauma, including glass from motor vehicle accidents, stab wounds, and gunshot wounds.⁶² Injuries range from involvement of the gland capsule, parenchyma, and/or duct, to injury of adjacent structures such as branches of the facial nerve. Treatment modalities include surgical repair and non-surgical management dependent on the structures damaged and the extent of their injury as well as the timing of

Fig. 44.15 (a) The main parotid duct runs in a trajectory that can be approximated by a line drawn from the tragus of the ear to the middle of the upper lip. (b) Any cheek laceration that involves this area must result in a high degree of suspicion for duct injury.

presentation. Frequently, injuries are not recognized at initial trauma evaluation.

The main parotid duct runs in a trajectory that can be approximated by a line drawn from the tragus of the ear to the middle of the upper lip. Any cheek laceration that involves this area must result in a high degree of suspicion for duct injury (Fig. 44.15). When ductal injury is present, injury to branches of the facial nerve is likely. Nerve injuries are covered elsewhere in this chapter.

Thorough wound inspection must be performed in order to determine the extent of damage to the gland and duct. Wound examination includes milking the parotid gland with intraoral examination of the duct to verify salivary flow. The anatomic location of the injury can also provide guidance for choice of management. Van Sickels and Alexander separated parotid duct injuries into three areas according to anatomic location:⁶³ injury of the duct during its course within the gland, over the masseter muscle, and anterior to the masseter. Lacerations of the gland can be managed with closure of the capsule and placement of a pressure dressing for 1 week. Frequent examination would reveal any salivary accumulation, which should be aspirated and the pressure dressing maintained.

A more frequently occurring injury is laceration of the duct over the masseter muscle. Injuries in this region can be treated by one of several methods including primary repair by microsurgical anastomosis, ductal repair with autogenous graft, ligation of the proximal duct to atrophy the gland, or non-operative management. The duct should be cannulated intraorally with lacrimal probes and if any doubt exists about the presence or quantity of saliva coming from the duct, the duct should be cannulated with a 20-gauge angiocatheter and injected with a small amount (1 ml) of methylene blue. If the duct is intact, this technique can provide information about the integrity of the parotid capsule. If the duct is transected, it will localize the distal cut end. The proximal cut end can then be localized by reapproximating the wound and following the lacrimal probe or catheter. The proximal cut end can also be found by milking the parotid gland and looking for saliva in the wound. If both proximal and distal stumps of the duct are visible, Stenson's duct can be cannulated with a hollow Silastic (Dow Corning, Midland, MI) catheter (16–22 gauge pediatric cardiac catheters are ideal) with a length of about 8–10 cm and the duct ends pulled together over the catheter. The stump ends can then be sutured with 9/0 or 10/0 nylon suture over the catheter, which maintains the integrity of the duct during suturing and prevents the posterior wall of the duct from being captured within the repair. The tube passed through the duct orifice into the mouth is sutured to the buccal mucosa. The catheter is maintained for 14 days along with external pressure dressing for 3 days.

If the cut ends of the duct will not reapproximate without tension, or when a segment of the duct is missing making direct anastomosis impossible, one option is to ligate the proximal duct allowing the gland to undergo atrophy. Drain placement may be necessary to prevent sialocele formation while the gland undergoes atrophy.⁶⁴ While this is the common method of treatment for duct ends which are not able to be anastomosed primarily, Chudakov and Ludchik describe their experimental study in dogs where venous autografts were used to complete the repairs.⁶⁵

When the duct injury occurs anterior to the masseter muscle, creation of an intraoral fistula may be indicated if duct repair is not possible. This is done by suturing a cannulated proximal duct after reimplanting it through the buccinator and buccal mucosa at the level of Stenson's papilla (Fig. 44.16). In cases where the duct is reanastomosed or an intraoral fistula created, the parotid gland is prone to obstructive sialadenitis. A course of antibiotics can be considered to prevent infection, and sugar-free lozenges can be used to stimulate saliva.

Conservative treatment of parotid duct injuries has also been advocated by some. Lewis and Knottenbelt describe a prospective study where they investigated the non-operative management of 19

Fig. 44.16 (a, b) A young patient presents with a gunshot wound to the face creating a through-and-through wound at the level of the parotid duct. (c) Examination reveals a parotid duct laceration. (d, e) The proximal duct is localized and cannulated with progressively larger lacrimal probes. (f) It is then cannulated with a hollow silastic tube. (g) The tube is replanted within the buccal mucosa at the level of Stenson's papilla and sutured into place. (h, i) The external wounds are closed in layered fashion. The catheter is maintained for 14 days with an external pressure dressing maintained for 3 days.

patients with confirmed parotid duct injuries.⁶⁶ All patients healed without surgical intervention. The 53% of patients who had minor complications healed with the use of sialogogues for fistulas and weekly aspiration of sialoceles. The remaining 49% healed without complication. The use of Botox has also been shown with good success to resolve parotid fistulas.⁶⁷

Botulism toxin type A inhibits salivary production by its anticholinergic effect on parasympathetic secretory motor fibers. Without constant salivary flow, the fistula will then resolve.

While sialography may be useful in the postoperative period to evaluate response to treatment, or to help identify undiagnosed parotid injuries, it has little

utility in the face of acute injury. That being said, sialography may help diagnose diffuse rupture of the gland parenchyma which can occur from blunt trauma to the parotid region.⁶⁸ Helical CT scan is a more useful diagnostic aid for acute traumatic injury to the salivary glands.⁶⁹ Magnetic resonance imaging (MRI) shows promise as a useful method of evaluation as better techniques are developed. High-resolution MRI studies, like sialography, are not practical tools for use in the acute injury setting; however, they may be useful for visualization of abnormal salivary duct systems following trauma. Using certain reconstructions of this image, fine anatomic details such as the parotid duct and facial nerve can be visualized – even within the gland itself. 3D reformations can also be created to allow visualization of the anatomy in precise planes.⁷⁰

Facial nerve

Injury to the facial nerve can have devastating functional and esthetic consequences. Facial nerve injury is likely to occur in penetrating injuries to the face and gunshot wounds where thermal injury radiates through large portions of tissue. Evaluation of an injury for facial nerve involvement is relatively easy to accomplish in a conscious, cooperative patient. Inability of the patient to move the muscles of facial expression suggests nerve transection. In an unconscious patient, examination will include the use of a nerve stimulator. Like evaluation for parotid duct injuries, anatomic location of the wound guides treatment for facial nerve injury. Nerve lacerations which occur medial to a line drawn from the lateral canthus of the eye to the mental foramen do not need primary repair due to their likelihood of spontaneous repair.⁶³ Wounds proximal to this line need to be explored for possible nerve injury with need for primary repair. Location of the wound with respect to the masseter muscle may also guide treatment, in that injuries which occur within the region of the masseter muscle and have involved the facial nerve are also likely to involve the parotid duct.

Ideally, facial nerve repair should be performed under magnification at the time of primary wound closure. If repair is performed within 48 hours of the injury, the use of a nerve stimulator can help identify the distal cut ends of the nerve; however, after 48–72 hours the nerve undergoes degeneration and the nerve stimulator is less likely to elicit muscle twitching from the distal nerve ends making their identification more difficult. The ends of the nerve should be cut to create a clean edge free from devitalized nerve tissue. The cut ends of the nerve should be mobilized and freed from the surrounding tissue, such that there is approximation without tension. The most important prognostic factor in facial nerve repair is tension-free anastomosis. While perineural repair is discussed throughout the literature as the most ideal, epineural repair may be more realistic. Two to three

sutures (8/0 or 9/0 monofilament) taken through the epineurium in a tension-free manner will approximate the segments and preserve the fascicles. When large nerve defects complicate the wound or tension-free approximation is not attainable, the use of interpositional grafts may be considered. Return of function may be delayed for up to a year after repair. Failure of the repair may be caused by tension or opening at the anastomosis or muscle or nerve fibrosis. Patients whose repair fails may be candidates for facial nerve rehabilitation.

Neck

Debates regarding the management of soft tissue injury to the neck have been documented dating from World War I to the present. After decades of changes in management protocols in efforts to optimize outcomes, a new strategy has emerged. The current strategy has been widely accepted in civilian settings across the US and has become available in large part by advances in technologic and diagnostic screening tools. Selective surgical intervention of traumatic injuries to the soft tissues of the neck in combination with strict observation of immediate and progressive indications for immediate surgical intervention have recently eclipsed the arguments in favor of mandatory surgical exploration for these types of injuries.

The neck serves as the conduit for many of the most fundamental organ systems, including the nervous system, aerodigestive system, and cardiovascular circulatory system. The neck houses the spinal cord, the laryngotracheal apparatus, the esophageal complex, and perhaps most critically the vessels supplying and draining oxygenated and deoxygenated blood to the brain, the carotid arteries, and the jugular veins, respectively. Penetrating neck injuries may cause damage to any of these or other critical structures, providing a challenging diagnosis for the surgeon and often a complex surgical plan. With advances in diagnostic imaging technology including computed tomographic angiography (CTA), multi-detector computed tomography (MDCT), and MRI, the surgeon's role in these cases has become clearer.

Mimicking general traumatic injury, most cases involving the soft tissues of the neck involve males in their 20s and 30s.⁷¹ Causation of injury is generally placed into three categories with few cases falling outside the top three: assault, motor vehicle accident, and self-inflicted injury. Different modalities of traumatic injury include both low and high-velocity bullet wounds, birdshot and buckshot shotgun wounds, and stab wounds to the neck.

Traumatic injuries to the soft tissues of the neck have long been anatomically classified into three zones.^{72,73} The most inferior zone, zone 1, extends from the sternal angle and clavicles to the inferior aspect of the cricoid cartilage. Zone 2 occupies the space from the cricoid cartilage to the angle and inferior border of the body of the mandible, the largest of

the three anatomic zones. The most superior zone, Zone 3 spans from the mandibular angle and body to the base of the skull. Penetrating neck trauma must also be classified in a second dimension, depth. Ordog uses a system of classification establishing depth of injury when categorizing shotgun wounds to the neck. Type 0 refers to the most superficial injury where pellets are in skin only, type 1 penetrating subcutaneous tissue, type 2 penetrating beyond deep fascia, and ultimately type 4 signaling extensive tissue damage.⁷⁴ Establishing a similar system to assess the depth of injury is often useful in determining management (i.e. penetrating injuries superficial to the platysma are often simply debrided and closed). Classification systems provide the structure necessary for proper assessment and management.

Clinical assessment of injury is often a complex task with these injuries. Patient presentation ranges from minimal discomfort to life-threatening airway compromise and profound shock. Presentation often depends on the systems affected, each component having the ability to present at different times post-injury. Notable are esophageal injuries which often go unnoticed upon admission due to their subtlety, yet 24-hour delay in diagnosis is associated with a significant increase in mortality.⁷⁵ Furthermore, an absence of initial signs or symptoms should be received with caution. Bell *et al.* reveal that Fogelman and Stewart's paper on penetrating neck injuries indicated that 70% of their patients with significant vascular injury showed no evidence of bleeding at the time of admission and 43% of their patients displayed no evidence of peripheral vascular collapse.⁷¹ Furthermore, 25% of patients with blunt vascular injuries will not display symptoms for 24 hours, and often a thromboembolic event resulting in acute ischemic stroke is the initial manifestation.⁷¹ Patients with any neck injuries, both penetrating and blunt, should be followed meticulously.

Signs and symptoms of injury differ not only in time of presentation, but also in proportion to which systems are affected. Hard signs of vascular injury, often reliable indicators of severe injury, include a bruit or thrill, expanding pulsatile hematoma, pulsatile hemorrhage, and pulse deficit, while softer vascular signs with less reliability include hypotension, stable hematoma, nervous system ischemia, and proximity to major vascular structure. Retropharyngeal or prevertebral air on cervical radiography should alert the surgeon to esophageal or hypopharyngeal perforation. Symptoms of esophageal injury include dysphagia, odynophagia, drooling, hematemesis, hoarseness, and air bubbling from a wound, while subcutaneous emphysema is often the most common presenting sign in significant injury to the aerodigestive tract.⁷⁵ Attention should be paid to the patient's complaints when conscious and any imaging or diagnostic armamentarium should be used as needed. MDCT, CTA, nasopharyngoscopy, laryngoscopy, barium swallow, bronchoscopy, and

four-vessel cerebral angiogram have all been validated as useful tools with relatively high sensitivity and specificity. The CTA has emerged as the most cost-effective and reliable screening tool to assess penetrating neck injury due to its speed, and ease of use by support staff.⁷¹ Bell cites a significant decrease in the number of neck explorations since screening with CTA, and a "virtual elimination of negative neck explorations".⁷¹

Although in near agreement regarding the selective surgical management of penetrating neck injuries, a clear list of injuries and signs and symptoms requiring mandatory surgical intervention is lacking. Although the lists are separate, most give high priority to airway collapse or compromise and extreme vascular injury. Ordog cites stage II hypovolemic shock not responding to fluid and blood resuscitation, stage III and IV shock, major pathology on physical exam, high-velocity bullet wounds, close range (<5 m) shotguns, and high-velocity shrapnel and explosive injuries all require mandatory surgical therapy.⁷⁴ Bell *et al.* include five indications for immediate surgical intervention regardless of zone, including exsanguinating hemorrhage, expanding hematoma, shock, airway compromise, and massive subcutaneous emphysema.⁷¹ While a shift in the field has been felt regarding selective management, the necessity of immediate surgical intervention for specific cases should be appreciated.

Patients will often present to the surgeon without cervical spine clearance and still in a collar from transport. Often judgment must be made regarding access to the neck wound while the patient is in the C-collar. It is generally felt that immediate urgent treatment of the penetrating neck wound should take precedence over concerns for the cervical spine, including removing a cervical collar to gain access to the injury when dealing with gunshot wounds. Extreme caution and scrupulous judgment should be used when addressing this dilemma.

Treatment of neck injuries is highly surgeon- and center-dependent and the contents of the neck often require a multidisciplinary approach. Differing surgical techniques are available for access, dependent on the zone of injury, balancing esthetics and ease of surgical exploration. Zone 1 injuries often require a combined transcervical and transthoracic approach, while zone 2 injuries are often accessed via a vertical incision anterior to the sternocleidomastoid muscle. Zone 3 injuries often necessitate horizontal incisions to adequately visualize their components. Management of the vascular component may be repair, bypass, ligation, or observation. Primary repair by reanastomosis is generally favorable, although grafting and ligation are sometimes necessary. Not all vascular injuries require surgical intervention and instead may be observed and followed in 1–2-week intervals. Such injuries include small intimal defects and pseudoaneurysms less than 5 mm. Routine repair of all carotid injuries is recommended by Bell in all

but comatose patients.⁷¹ The majority of esophageal injuries resulting in death occur from mediastinitis and sepsis, thus direct esophageal repair utilizing a one- or two-layered technique should be used to prevent abscess formation. Esophageal surgeries secondary to penetrating neck trauma have high rates of mortality. Management of the esophageal, laryngeal, and tracheal components of the injuries should be approached by the appropriate services.

Follow-up on patients with neck trauma should be frequent and thorough. In the first week many patients require additional support. Bullet wounds and other penetrating injuries display high rates of infection, with deeper penetrating wounds being more susceptible. Prophylaxis is recommended in many of these cases and should be contemplated by the surgeon. Vascular injuries have been shown to predispose certain patients, especially those with existing atherosclerosis, to thromboemboli and stroke.⁷⁵ Administration of systemic anticoagulation therapy has decreased this problem significantly. Protracted observation is recommended.

Scalp

The scalp consists of five layers: skin, subcutaneous tissue, the galea aponeurosis, loose areolar tissue, and pericranium. It is thick, inelastic, and has multiple extensive vascular anastomotic complexes which make achieving hemostasis difficult after injury. Severed blood vessels lack the ability to contract due to the inelastic nature of the scalp and can contribute to life-threatening hemorrhage after extensive laceration. It is important to assess the amount of hemorrhage that has occurred from the time of injury to the time of repair in these cases, especially for complex scalp lacerations in the pediatric population.

Treatment of lacerations of the scalp is similar to those of the face. The wound must be adequately cleaned, debrided, and reassessed. Thorough wound exploration can detect skull fractures that are less likely to show up on skull films.⁷⁶ Hemostasis can be achieved with electrocautery, Raney clips, or direct pressure, but control of bleeding prior to closure allows for easier examination and approximation. Direct pressure with gauze and pressure dressing can be applied and left in place for 30–60 minutes to control bleeding.⁷⁷ Local anesthesia with epinephrine also aids hemostasis. Hair removal is not necessary prior to closure and has not been shown to decrease infection rates.⁷⁸ Shaving hair from the skin increases the risk for wound infection; therefore, if it is necessary to remove hair, it should be cut with scissors.⁷⁹

A relatively new method of closing simple scalp lacerations is the hair apposition technique (HAT). Four to five strands of hair are taken in a bundle on either side of the laceration and crossed over the laceration. A mosquito hemostat is used to make one twist of the hairs to approximate the wound. A drop of tissue adhesive is then used to secure the hair twist.

In a randomized controlled multicenter trial, the HAT method was found to be at least as acceptable if not superior to standard suturing methods.⁸⁰ Advantages of the technique include less pain, shorter treatment time, high patient acceptance, no need for suture removal, less scarring, and less wound dehiscence. Contraindications to this method of scalp repair include contaminated, extensive lacerations, lack of hemostasis, and inadequate length of hair.

Simple lacerations of the scalp can also be closed primarily with sutures; 3/0 or 4/0 non-absorbable suture such as nylon or colored polypropylene makes for easy retrieval. Stapling of scalp lacerations has also been shown to be an effective, efficient, and cosmetically acceptable closure technique.⁸¹ When lacerations involve the galea, it needs to be approximated as much as possible and closed with resorbable sutures. This layered closure will prevent cosmetic deformity of the forehead associated with disinsertion of the frontalis muscle. Closure of this layer will also protect the underlying connective tissue, with its rich bed of emissary veins and direct connection to intracranial veins, from bacterial infection.

For large avulsive scalp defects, microsurgical reconstruction is a reliable option for providing coverage. Replantation of an acutely avulsed scalp and free flap coverage may provide better stability than traditional skin grafts.^{82,83} For infected or heavily contaminated wounds delayed closure or closure by secondary intention should be considered (Fig. 44.17). If pericranium is intact, a split-thickness skin graft can be used to cover the defect. If pericranium is missing, the skull must be decorticated with burr holes in order to allow secondary healing or in order for the skin graft to take (Figs 44.18).

After repair, large scalp lacerations may necessitate a pressure dressing in order to prevent hematoma formation. After 48 hours the pressure dressing can be removed and normal wound care can continue.

Postoperative untoward results

Delayed healing

Delayed wound healing is failure of the systematic progression through the phases of wound healing. Three classic phases are generally described in terms of wound healing: inflammation, proliferation, and maturation. Abnormal healing may manifest as a prolongation or failure of completion of any of these phases, resulting in problems such as infection, chronic inflammation, hypo- or hypergranulation, or over-repair.

Infection

Normal wound healing can be inhibited by high levels of bacteria. Bacteria and their by-products maintain a balance with host resistance in tissues.

Fig. 44.17 (a–c) Large contaminated avulsive scalp lacerations may be allowed to heal by secondary intention if pericranium is intact. Wet-to-dry dressings allow for mechanical debridement of the wound during healing.

Fig. 44.18 (a, b) A young female patient presents 5 days postassault with a large infected scalp laceration. The wound was cleaned, debrided, packed, and allowed to heal secondarily. (c–e) After adequate granulation of the wound, the wound was pexed. Monocortical screws were placed at the temporal crest of the skull. Sutures were placed through the temporalis and the muscle was anchored to the bone via the screws. (f) The wound was then able to be closed. (g) The wound is intact 2 weeks after closure.

Once this balance is disrupted by either an impairment of the host defenses or an increase in bacterial load, infection may result. Research has shown us that critical tissue levels of bacteria, a growth of more than 100,000 organisms per gram of tissue is consistent with clinical infection and delayed wound healing.⁸⁴ The face, due to its high vascularity, may be able to tolerate higher bacterial loads before infection ensues.

Diagnosing postoperative wound infection can be difficult due to the effects of cytokine release which look the same in both normal and abnormal healing: erythema, pain, edema, and increased temperature. A wound can be considered infected if purulence is present. Definitive diagnosis may be made from wound tissue biopsy cultures which reveal the presence of beta-hemolytic streptococci, or the presence of a critical level of bacteria (greater than 10^5 per gram of tissue). Due to their time requirement, tissue cultures may not be practical for diagnosis in some cases; however, Gram stain can be performed in 15 minutes and be useful for determination of a critical level of bacteria. If even one organism is visible upon rapid slide Gram stain technique, it is inferred that more than 10^5 organisms are present within the wound.⁸⁴

Unlike medical infections which are amenable to systemic antibiotic therapy, wound infections resolve with operative treatment. Presence of foreign bodies, sutures, necrotic tissue, or hematomas tip the balance in favor of the bacteria. Incision and drainage, debridement of necrotic tissue, excision of foreign bodies, and evacuation of hematomas all work at the site of infection to decrease the bacterial inoculum and prime the tissue for wound healing.

Chronic inflammation

Wounds subject to long-standing levels of bacteria fail to progress through the phases of wound healing. Inflammatory cytokines such as interleukin-1 and tumor necrosis factor- α are sustained at high levels within the wound and inhibit growth factor production.³⁷ Oftentimes, host defenses are impaired contributing to chronicity of the wound. Determining, by clinical evaluation alone, when a chronic wound can be closed – whether by direct closure, graft or flap – is difficult. The appearance of epithelialization is not predictable because this process can continue in sub-optimal wound healing, even when granulation has not progressed as well, thus forming a crater in the skin surface.

Quantitative bacterial testing (i.e. wound tissue culture) is a definitive method to determine when a wound has less than 10^5 bacteria per gram of tissue. When critical colonization is established, the wound cannot be closed and methods to decrease the bacterial contamination of the wound must be employed in order to optimize the wound for successful closure. Surgical debridement, frequent

cleansing, protection from continued trauma, and, if indicated, occlusion of the wound are techniques to optimize the wound. Other, more controversial techniques deserve discussion.

The use of systemic antibiotics is usually not indicated for chronic wounds except when sepsis, osteomyelitis, cellulitis, or other signs of invasive infection are present. If the chronic wound is associated with a mild local infection where the erythema present is within 1 cm around the perimeter of a wound, systemic antibiotics are not indicated.⁸⁵

When local measures can no longer control the infection, systemic antibiotics are indicated. However, many wounds may be amenable to local treatment before infection becomes invasive. Because ischemia may reduce a wound's bioavailability to a systemic antibiotic, topical antibiotics may be a good option for treatment of local infection. Topical antibiotic and topical antiseptic preparations have a lower incidence of systemic effects but the incidence of bacterial resistance with their use is unclear. Some research shows that resistance is decreased, while other studies claim that topical antibiotics are a major cause of antibiotic resistance.^{86,87}

In randomized controlled trials, enzymatic debridement and silver-releasing hydroalginate dressings have shown to be favorable for healing of chronic wounds.^{88–90} Enzymatic debridement is sometimes used after an initial sharp surgical debridement or in place of sharp debridement if the patient's medical history is complicated by a bleeding disorder; however, it is rarely needed in the maxillofacial region.

Over-repair

Keloids and hypertrophic scars are two types of abnormal scarring that develop as a result of soft tissue trauma. Keloids and hypertrophic scars fall into the category of fibroproliferative disease (FPD) of the skin, of which the pathogenesis is unknown. Hypertrophic scars present as raised, reddened, itchy scars that spontaneously flatten and soften, whereas keloids remain raised and thickened and may undergo periods of quiescence alternating with periods of growth. Hypertrophic scars are red in appearance and pruritic due to the increased vascularity. Keloids may be painful.

Keloids and hypertrophic scars both exhibit fibrous outgrowth; however, hypertrophic scars remain within the borders of the wound as opposed to keloids, which enlarge over the wound confines and may continue to grow indefinitely. While clinically and histologically similar, keloids and hypertrophic scars may not represent varying degrees of a single disease entity. Because of such differences in behavior, the pathogenesis may be completely different. Until the pathophysiology becomes clearer, patients with abnormal scarring will have little reassurance that any particular mode of treatment may eliminate their pain, pruritis, or chance of recurrence. Multiple

treatment modalities exist for keloids and hypertrophic scars; however, no single method has demonstrated superiority.

Compression therapy is a method employed to decrease scar formation and is commonly used in burn patients by the use of compression garments. The mechanism is thought to be that the hypoxic effect of the compression on fibroblasts causes fibroblast degeneration and ultimately less collagen formation. Another theory is that the mechanical effect of the compression causes the collagen fibers to be laid down in flatter ribbons rather than whorls. The use of compression is usually not practical for the prevention of keloid recurrence or minimization of scarring in the head and neck with the exception of ear keloids. Soft tissue trauma induced by piercing of the earlobe or auricle may lead to keloid formation in some patients (Fig. 44.19). Specialized pressure earrings or magnets may be worn continuously for 6 months after excision of a keloid or hypertrophic scar in an effort to reduce the chance of recurrence.^{91,92}

Silicone gel sheets which work by hyperhydration of the subcutaneous tissue, have shown some efficacy in reducing the symptoms and appearance of keloids; however, in the head and neck region, this method is not practical.⁹³ The occlusive nature of the sheets prevents water loss which in turn decreases capillary action, resultant inflammation, and subsequent colla-

Fig. 44.19 Soft tissue trauma induced by piercing of the earlobe or auricle may lead to keloid formation in some patients.

gen formation. The sheets should be applied after re-epithelialization and be worn for at least 12 hours a day for 1 month.⁹⁴

Intralesional steroid injection is a common method of treatment for keloids. Steroid injection may help to alleviate some of the pain and pruritis associated with these lesions as well as soften them. The mechanism, like most other therapies targeted at management of fibroproliferative disease, is decrease of production of collagen through fibroblast inhibition. Triamcinolone acetonide (Kenalog; Bristol-Myers Squibb, Princeton, NJ) is often used and injected at a concentration of 40mg/ml.⁹⁵ Intralesional steroid injection is most often used as an adjunct to excision or debulking of the lesion. Side-effects of this treatment include pain from injection, hypo- or hyperpigmentation, skin necrosis and skin atrophy, as well as systemic effects of steroid absorption.

Electron beam radiation after surgical excision of keloids has been used to prevent recurrence; however, irradiation carries the risk of inducing malignant tumors and increasing pigmentation of the lesion, and the method lacks standardization. That is, optimal doses to prevent recurrence vary by site and a standard protocol has yet to be determined. When compared to intralesional steroid injection following keloid excision in a randomized controlled trial, radiotherapy showed better success in the form of decreased recurrence rate and better patient compliance.⁹⁶

Some research has suggested that intralesional injection of interferon- α 2b into hypertrophic scars improves scar quality which is due to a resultant decrease in number and function of fibrocytes.⁹⁷ However, as a method to treat keloids, interferon- α 2b has been less successful. Randomized controlled clinical trials failed to show the benefit of interferon- α 2b either as an adjunct to surgical excision or as a stand-alone therapy.^{98,99}

The morbidity associated with keloids and hypertrophic scars can be significant and range from poor cosmesis to severe pain and pruritis. An emphasis of research on prevention, in addition to treatment, has occurred in an effort to eliminate some of the potentially devastating effects of fibroproliferation disease. Prevention of fibroproliferation disease is the subject of both *in vitro* and *in vivo* studies. The local application or injection of basic fibroblast growth factor (bFGF) immediately after closure of surgical incisions has been shown to reduce scar formation.¹⁰⁰ Fibroblast growth factor has also shown promise in decreasing healing time and promotion of better quality of healing in chronic traumatic wounds.^{101,102} The mechanism by which bFGF promotes healing with a decrease in scar formation is not entirely understood; however, one theory is based on the fact that bFGF is a potent angiogenesis inducer.¹⁰⁰

Other modalities to decrease keloid recurrence and lessen hypertrophic scar symptoms include cryotherapy, laser therapy, 5-fluorouracil (5-FU) or imiquimod application, and intralesional bleomycin.

The limitations of use for these methods vary from hypo- to hyperpigmentation, pain and burning from injection or application, high recurrence rates, and unknown efficacy due to lack of research. Until the pathophysiology of fibroproliferative disease is better understood and a specific therapy developed, combination therapy may be the most effective treatment of keloids and hypertrophic scars.

Chapter 45

Cleft Lip and Palate: An Overview

Radhika Chigurupati, Andrew Heggie, and Krishnamurthy Bonanthaya

This chapter is a comprehensive overview on management of cleft lip and palate deformities. Epidemiology, etiology, embryology and genetics are discussed in the first half of this chapter. The importance of interdisciplinary team care is emphasized, and the sequence of treatment from birth to adulthood is presented. The surgical principles of correction of both primary and secondary deformities of cleft lip and palate are discussed in the second half of this chapter.

Global burden of birth defects: cleft lip and palate

More than four million children are born with birth defects worldwide every year. Craniofacial anomalies comprise a large fraction of all human birth defects, less frequent only than congenital heart disorders and clubfoot. Cleft lip with or without palate (CL/P) is the most common craniofacial birth defect with an estimated quarter of a million affected babies born each year in the world. This malformation shows considerable variation across geographic regions and ethnic groups and has significant medical, psychological, social, and economic ramifications.¹ It is a costly public health problem with an average lifetime treatment cost per child in the US estimated to be roughly \$101 000.²

The World Health Organization (WHO) and most cleft organizations across the globe recommend interdisciplinary care by a team of specialists. In reality, however, surgical and non-surgical treatment is often fragmented and dictated by socio-economic factors and access to medical facilities. In developing countries, particularly in rural areas, care is often neglected due to social beliefs and lack of awareness, or initiated late due to restricted resources and inadequate access. The delay in treatment and intermittent care by local or overseas cleft mission surgeons, combined with incomplete follow-up, results in poor outcomes with unnecessary complications. More recently, some humanitarian non-profit organizations supporting cleft care have changed their aid philosophy. They are identifying centers with a potential to deliver quality care in low- and middle-income countries and

providing support for the physicians, staff, and hospital infrastructure, helping to establish parameters of care, as well as monitoring treatment outcomes at these centers.³

Birth defects are emerging as a cause of neonatal mortality in countries that have made progress in controlling infectious diseases and malnutrition. The strategies proposed to reduce the global impact of birth defects include: (1) effective family planning, genetic counseling, and prenatal diagnosis; (2) education for couples to decrease maternal exposure to avoidable environmental risk factors such as tobacco, alcohol, and teratogenic medications; (3) improving periconception maternal intake of micronutrients such as folic acid (400µg); and (4) improving the availability of medical and surgical care locally for the affected infants. National leadership and commitment are essential for proper surveillance of birth defects, infant mortality, and to monitor the clinical and cost effectiveness of various interventions.^{4,5}

The WHO initiative for collaborative craniofacial anomalies research has identified areas of uncertainty in clinical care and efforts are being made to conduct trials with sufficiently large samples of patients to provide evidence for treatment strategies. Initial research efforts have focused on addressing surgical, anesthetic, and nursing care for patients with craniofacial anomalies in developing countries. Surgical techniques for repair of various cleft sub-types and correction of velopharyngeal insufficiency are being evaluated. Adjunctive services such as use of prophylactic ventilation tubes, presurgical orthopedics, psychological counseling, speech therapy, and feeding interventions before and after surgery are also being monitored and assessed. An international database of craniofacial anomalies has been established to improve answers to questions relevant to individuals with cleft and craniofacial anomalies, their families, and health care providers.⁶

Epidemiology

Cleft lip with or without palate (CL/P) has an average birth prevalence of 1:700 ranging from 1:500 to 1:2000, depending on the race (Table 45.1). There are wide ethnic variations with highest occurrence in Native Americans (3.6:1000), followed by Asians (2.1:1000 Japanese births and 1.7:1000 Chinese births), Caucasians (1:1000), and lowest in those of African descent (0.3:1000). Cleft of palate only (CP), which differs genetically from CL/P, has a birth prevalence rate of 1:2000 and is more similar across all populations.⁷⁻¹³ About half of the oral clefts involve lip and palate (46%), a third of the clefts involve only the palate (33%), and clefts of lip alone account for 21%. CL/P is more often unilateral than bilateral and more common in males than females. The unilateral defects occur more often on the left side than the right side. Clefts of lip occur in the ratio of 6:3:1 for unilateral

Table 45.1 Epidemiology of oral clefts.

Distribution of oral clefts
Cleft lip and palate 46%
Cleft palate only 33%
Cleft lip only 21%
Cleft lip with or without palate
Average birth prevalence 1:700
More common in males
Unilateral > bilateral
Left side > right side
Association with other anomalies 10%
Cleft palate only
Average birth prevalence 1:2000
More common in females
Association with other anomalies 50–60%

left, unilateral right, and bilateral.¹⁴ CP is more common in females and more often associated with other developmental anomalies.

Clefts are referred to as non-syndromic and syndromic, based on their association with other anomalies. About 50% of CP and 10% of CL/P are associated with a syndrome.¹⁵⁻¹⁷ Some common syndromes associated with cleft lip and palate include Van der Woude, Treacher Collins syndrome, Down syndrome, oro-facial digital syndrome, Opitz syndrome, craniofacial microsomia, and fetal alcohol syndrome.¹⁸ Nearly half of the syndromic cleft palate presentations are associated with the triad of micrognathia, glossoptosis, and airway obstruction (Pierre Robin sequence). The most common syndromic presentations of this triad are Stickler's syndrome, accounting for 25%, and velo-cardio-facial (VCF) syndrome, accounting for 15% of all syndromic cleft palate individuals.¹⁹

Etiology and genetics

Non-syndromic CL/P is a complex trait with multifactorial etiology, resulting from gene–gene and gene–environmental interactions. Identification of key genes contributing to the genesis of orofacial clefts will help in early diagnosis, disease prevention, or possibly developing adjunctive therapies. The most recent estimates suggest that anywhere from 3–14 genes contribute to cleft lip and palate.^{20,21} Candidate genes and loci responsible for non-syndromic CL/P have been identified on chromosomes 1, 2, 4, 6, 11, 14, 17, and 19.²²⁻²⁴ Two genes IRF6 and MSX-1 now seem to explain about 15% of non-syndromic CL/P. Mutations in IRF6 lead to Van der Woude and popliteal pterygium syndromes. Mutations in other genes, TBX22, FGFR1, and P63, also contribute to syndromic clefts.^{25,26} Aberrant transforming growth factor beta-3 (TGF-β3) signaling plays a role in the pathogenesis of cleft palate.

Environmental factors that contribute to the etiology of facial clefting disorders include cigarette smoking,^{27–30} folic acid deficiency during the periconceptional period,^{31,32} and maternal exposure to alcohol and teratogenic medications such as retinoids, corticosteroids, and anticonvulsants (phenytoin and valproic acid).²³ Co-sanguineous marriages, maternal diabetes, and obesity have also been linked to an increased risk of orofacial clefts. Less consistent associations have been found between clefts and maternal viral infections such as rubella and varicella.^{6,19}

Studies conducted to determine the risk of having a child with CL/P show that every parent has about a 0.14% (1:700) chance of having a child with a cleft. The risk of recurrence of a cleft condition is determined by a number of factors, including the number of family members with clefts, their relationship to family members with clefts, race and sex of the affect-

ed individuals, and the type of cleft. Studies show that the recurrence risk for first-degree relatives is about 3.3% for CL/P and for isolated CP it is 2%.³³ Once parents have a child with a cleft the risk of having a second child with a cleft is about 2–5%, and after two affected children that risk rises to 9–12%.^{34,35} In twins with CL/P and those with isolated CP, the concordance is far greater for monozygotic twins than for dizygotic twins.¹⁹ Parents and young adults should be counseled appropriately by a geneticist so that they are in a better position to make decisions about future pregnancies.

Embryology

The embryologic development of the face begins at 4 weeks after conception from the neural crest ectomesenchyme that forms five prominences; the fronto-nasal process, and paired maxillary and mandibular processes surrounding a central depression. During the fifth and sixth weeks of embryonic development, bilateral maxillary processes derived from first brachial arch fuse with the medial nasal process to form the upper lip, alveolus, and the primary palate (Fig. 45.1). The lateral nasal process forms the alar structures of the nose. The lower lip and jaw are formed by the mandibular processes.

This process of formation of the face is the consequence of a cascade of processes that involve cell proliferation, cell differentiation, cell adhesion, and apoptosis. Failure or error in any of these cellular processes that lead to fusion of the medial nasal process with the lateral nasal and maxillary process can cause orofacial clefts (Fig. 45.2). The molecular events that underlie these cellular processes are under the control of a strict array of genes that include fibroblast growth factors (FGFs), sonic hedgehog (SHH),

Fig. 45.1 (a) Schematic diagram showing embryonic development of face at 6 weeks. (b) Electron microscopy showing the development of face of a 37-day-old human embryo. The nasal pit (NP) is surrounded by the medial nasal process (MNP) and lateral nasal process (LNP) and maxillary process (MAX). (Adapted and redrawn from Sperber, GH. *Craniofacial Development*. Hamilton: BC Decker Inc, 2001. Reproduced with permission.)

Fig. 45.2 Orofacial clefts resulting from errors during embryonic development of face. (a) Unilateral cleft of upper lip. (b) Bilateral cleft of the upper lip. (c) Midline cleft of the upper lip and nose. (d) Median mandibular cleft. (Adapted and redrawn from Sperber, GH. *Craniofacial Development*. Hamilton: BC Decker Inc, 2001. Reproduced with permission.)

bone morphogenic proteins (BMPs), and members of the transforming growth factor beta (TGF- β) superfamily and other transcription factors.¹⁰ The formation of the secondary palate begins during the sixth week after conception from the two palatal shelves, which extend from the internal aspect of the maxillary processes. During the eighth week, these bilateral maxillary palatal shelves after ascending to an appropriate position above the tongue, fuse with each other and the primary palate. A disruption in the fusion of these embryonic components can occur due to delay in elevation of the palatal shelves from vertical to horizontal, defective shelf fusion, or post-fusion rupture resulting in a cleft of the secondary palate (Fig. 45.3).³⁶

Classification

In order to standardize documentation and communicate effectively, various types of classification systems have been described. The early Veau classification included groups 1–4 with increasing severity of clefting:

- group 1 – cleft of the soft palate;
- group 2 – cleft of the hard and soft palate up to incisive foramen;
- group 3 – complete unilateral cleft lip and palate;
- group 4 – complete bilateral cleft lip and palate.

However, this classification is not always adequate to document the variations. The more sophisticated schematic diagrams, such as the one described by Kernahan and Stark have been used recently (Fig. 45.4).³⁷ Berkowitz used a simple classification for labio-palatine clefts:

1. Clefts of lip and alveolus.
2. Clefts of primary (including lip) and secondary palate.
3. Clefts of secondary palate only.
4. Submucous cleft.

Interdisciplinary management of the cleft individual

The idea of interdisciplinary care is to coordinate treatment by multiple specialists in a timely fashion with an aim of achieving normality in all aspects, including feeding, breathing, speech, hearing, alignment of teeth, appearance, and overall psychological and physical development. The timing of surgical and non-surgical interventions should coincide with the physical, cognitive, and social development of the child (Table 45.2). Cleft teams generally include a craniomaxillofacial surgeon, pediatrician, nurse practitioner, speech pathologist, orthodontist, social worker, and geneticist. Experience in Scandinavian countries and a multicenter Euro-cleft study have

Fig. 45.3 Coronal scanning electron microscopy photos of human embryo showing the stages of formation of the palate at 8–9 weeks. (a) Development of palate showing palatal shelves and tongue position. (b) The vertical orientation of the palatal shelves on either side of tongue. (c) Palatal shelves elevate and (d) fuse with each other and the nasal septum in the midline.

demonstrated that standardization, centralization, and participation of surgeons who perform a large number of cleft procedures produce better surgical results in terms of speech, appearance, and facial growth.³⁸ However, this cannot be applied to all countries, particularly those with a high volume of cleft individuals and a limited number of care facilities.

Prenatal diagnosis

Interdisciplinary team care begins with prenatal diagnosis and parental counseling. With the advent of sophisticated high resolution three-dimensional (3D) ultrasonography and genetic tests for screening of birth defects, intrauterine diagnosis of cleft lip is possible. Early diagnosis of a cleft of the lip should alert the obstetrician to the possibility of other malformations that may require further investigations. While early diagnosis may help parents to be better prepared, the advent of such a capability raises both ethical and psychological issues, such as dilemma of termination of birth. Physicians and surgeons have to inform parents that CLP in the absence of other major systemic anomalies is a treatable non-life-

threatening condition. The cleft team also can discuss feeding issues and timing of lip and palate surgery, and can help establish contact with support groups for the family.³⁹

Transvaginal ultrasonography may reveal a cleft of lip as early as 11 weeks whereas 16–20 weeks is ideal for transabdominal ultrasonography. Several factors may influence the accuracy of ultrasound studies: sophistication of the scanning equipment; experience and skill of the sonographer; number of weeks into pregnancy; position of the baby while scanning; amount of amniotic fluid; maternal body structure; and severity of cleft.

Premaxillary protrusion is an important clue to the presence of cleft lip and cleft palate and may be more conspicuous than the cleft itself. The presence of a paranasal echogenic mass favors the presence of bilateral cleft lip and cleft palate. Clefts of palate alone are rarely visualized on ultrasound.⁴⁰ The majority of the cases of orofacial clefts are detected antenatally. A recent study by Johnson *et al.* showed that the frequencies of prenatal diagnosis for cleft lip and palate, cleft lip only, and CP only were 33.3%, 20.3%, and 0.3%, respectively.⁴¹ Although the benefits of fetal healing have been well documented, at this time there is no indication for intrauterine repair of the cleft lip deformity as the risk of fetal surgery is far too

Fig. 45.4 Kernahan and Stark classification of clefts. Kernahan’s striped-Y classification: areas 1 and 5 represent the right and left sides of nasal floor, 2 and 6 represent the right and left sides of the lip respectively. The alveolus is represented by areas 3 and 7, the hard palate anterior to the incisive foramen by areas 4 and 8, the hard palate posterior to the incisive foramen by areas 9 and 10, and the soft palate by area 11. (From Millard Jr DR. The unilateral deformity. In: *Cleft Craft: The Evolution of its Surgery*, Vol 1. Boston, MA: Little, Brown, 1977; 52. Reproduced with permission. Copyright © D. Ralph Millard, Jr.)

Table 45.2 Timing of treatment in the cleft patient.

Prenatal
Diagnosis and parental counseling
0–6 months
General assessment for associated anomalies ENT evaluation – breathing, feeding, swallowing, and hearing Presurgical orthopedics (0–3 months) Primary lip repair (3–4 months)
6 months – 2 years
Speech and oral sensory motor assessment Grommets/ear tubes (as needed) Primary palate repair (9–12 months)
Preschool: 3–5 years
Dental care Speech assessment and therapy (continue as needed) Assess need for lip revision
Childhood: 6–12 years
Correction of velo-pharyngeal dysfunction (as needed) Orthodontic treatment – phase I Alveolar cleft repair (8–11 years)
Adolescence: 13–18 years

high both for the fetus and mother for correction of this non-life-threatening condition.

General assessment

Every child born with a CL/P should be thoroughly assessed by complete physical examination and necessary diagnostic tests to check for associated systemic abnormalities, including congenital heart, renal, or airway anomalies. If the child is delivered in a non-medical facility or a small hospital they should be referred to a tertiary hospital with specialists or a craniofacial team for further evaluation. A proper airway assessment, and counseling for nutrition and feeding should be initiated immediately.

Feeding and nutrition

Feeding is one of the first concerns in a child born with a CL/P. Parents should be taught how to feed the baby and informed about various feeding nipples that can deliver more milk under less pressure. The goal is to provide adequate nutrition to satisfy the caloric requirements and avoid failure to thrive. The team nurse generally provides the parents with information on feeding before birth or immediately after birth. Children with cleft lip only without a cleft palate may have some difficulty in creating a seal around the nipple but generally can be breast fed before and after lip surgery. However, the presence of a cleft palate makes it difficult to create a negative pressure that is necessary to feed. Four randomized clinical trials conducted with a total of 232 babies showed that squeezable bottles may be easier to use than rigid bottles for children with CL/P. There was no statistical difference found in growth outcomes of children with CL/P who were fitted with a passive palatal appliance to help with feeding and those without an appliance.^{42,43} A feeding tube is rarely necessary except in infants with other associated anomalies, particularly airway anomalies.

Ear, nose, and throat evaluation

A proper airway assessment should be priority for a newborn with congenital craniofacial anomalies. Infants are obligate nasal breathers. It is important to check if there is obstruction at any level in the upper or lower airway, including the nares and choanae. Children born with a cleft of the palate may have associated micrognathia, glossoptosis, and airway obstruction (Fig. 45.5). In these children, one should look for signs of increased effort while breathing, stridor, weight loss, and failure to thrive. Parents should be informed to watch for an abnormal breathing pattern or respiratory distress, particularly during upper respiratory tract infection. If there are signs of airway obstruction, a pediatric otolaryngologist should be consulted to perform an endoscopic evalu-

Fig. 45.5 Child with Pierre Robin sequence (PRS) showing a wide cleft of palate, small lower jaw, and a retropositioned tongue in the cleft obstructing the airway.

ation of upper and lower airway to look for possible cause of obstruction.

An audiology assessment is recommended soon after birth to check for hearing abnormalities. Children with cleft palate exhibit a higher frequency of otitis media prior to palate repair than those without clefts. Middle ear ventilation disorders due to eustachian tube dysfunction can cause conductive hearing loss. This can also contribute to speech and language delay in these children. Although not as common as conductive hearing loss, sensorineural hearing deficits exist within the cleft population, and it has an effect on speech perception and clarity, as well as auditory comprehension skills.^{44,45} Early speech and language stimulation and an initial speech evaluation no later than 6 months after birth are recommended for children with clefts of palate.

Presurgical orthopedics

The benefits of presurgical orthopedics include better alignment of the alveolar segments and premaxilla, tension-free approximation of the cleft lip edges, and improvement of nostril symmetry and shape. Presurgical orthopedics was introduced in the management of clefts by McNeill and Burston. They initiated the use of a palatal acrylic plate in order to bring the collapsed maxillary alveolar segments into proper alignment prior to lip surgery. Latham described use of an active expansion device to align the collapsed lateral maxillary segments and retract the premaxilla in complete bilateral clefts, and to achieve symmetry of the alveolar arch in complete unilateral clefts.^{46,47}

Grayson and others have shown that gentle application of presurgical orthopedic forces to mold the alveolar segments and the nostrils within 0–3 months of birth has shown some benefits in correction of the nasal deformity in children with complete bilateral CLP and wide unilateral clefts. Nasoalveolar molding increases the surface area of the nasal mucosal lining, and also helps with elongation of the columella and making the columella upright. This preoperative expansion of the nasal lining allows suturing of interdomal cartilages without tension and decreases widening of the nose (Fig. 45.6).^{48–51}

Fig. 45.6 (a) Baby with a bilateral cleft lip and palate showing protrusion of premaxilla before nasoalveolar molding. (b) Nasoalveolar molding appliance. (c) Nasoalveolar molding appliance in position to expand nasal soft tissues and align the alveolar cleft segments. (d) Note the position of premaxilla in frontal view after nasoalveolar molding. (Courtesy of Dr Oberoi, UCSF Center for Craniofacial Anomalies.)

There is a wide variation in the availability of expertise and cost of treatment when it comes to infant presurgical orthopedics or nasoalveolar molding. In recent years, several centers have reported the adoption of this technique to improve the outcomes of lip and nose repair, especially in complete bilateral CLP.^{52,53} It is important to evaluate these recent studies critically for their overall clinical and cost effectiveness. Non-surgical lip adhesion with tape is a cost-effective and simple technique that can bring the alveolar segments closer to facilitate cheiloplasty in infants with wide clefts of the lip and palate (Fig. 45.7).

Cleft lip repair

The goal of primary lip repair is to reconstruct a functional lip with minimal scarring and normal appearance. The timing for primary lip repair is usually between 3 and 6 months after birth. Most craniofacial centers follow the rule of ten's to ensure that the

infant is fit for the surgical procedure. This rule implies that the infant should be at least 10 weeks of age, weigh at least 10 lbs, and have a hemoglobin level of at least 10 g/100 ml. Some centers have reported lip repair in children with lower hemoglobin levels (8 g/100 ml) with no deleterious effects. In low- and middle-income countries, infants are often malnourished and proper feeding and nutrition counseling is essential to prepare them for lip surgery by 3 months.⁵⁴ Lip repair is performed under general anesthesia with an Oral RAE[®] endotracheal tube taped to the midline of lower lip without distorting the commissure. Postoperative care includes keeping the wound clean by preventing crusting and using antibiotic cream; in some centers arm restraints are also used for 7–10 days.

A surgical lip adhesion may be preferred as an initial surgical procedure within 6–8 weeks after birth in some centers. Lip adhesion helps to align the maxillary alveolar segments and achieve a tension-free definitive lip repair at a later date. Good approximation of the alveolar segments also allows the surgeon

Fig. 45.7 (a–d) These photos illustrate that simple presurgical orthopedic techniques, such as lip taping, can be used to align the cleft alveolar segments prior to lip repair.

to perform a gingivoperiosteoplasty at the time of definitive cheiloplasty. The disadvantages of converting the complete cleft lip to an incomplete one by lip adhesion are: the need for an extra operation and the possibility of excising more tissue at the time of definitive lip repair. Non-surgical orthopedic techniques during the first 6–8 weeks after birth, as described earlier in this chapter, can produce good alignment of the alveolar segments.

Unilateral cleft lip

Surgical anatomy

Unilateral cleft lip is an asymmetric deformity that presents with a multitude of inherent anatomic variations (Fig. 45.8). The most visible anatomic abnormalities of the complete unilateral cleft lip and nose deformity are due to the abnormal position of the orbicularis oris muscle. After fetal dissections, Fara noted that in a complete cleft lip, the fibers of the orbicularis oris muscle instead of proceeding horizontally from the commissure towards the midline turn upward along the margins of the cleft. The fibers of the orbicularis terminate medially beneath the base of the columella and laterally beneath the alar base and periosteum of the piriform rim.⁵⁵ It is these abnormal muscle attachments and pull, that cause the typical bulge on the unrepaired cleft lip, distortion of the ala of the nose, and deflection of anterior nasal spine and septum of the nose. The nasal deformity is proportionate to the severity of clefting. In the complete unilateral cleft lip and palate deformity, there is slumping of the alar cartilage on the cleft side resulting in an asymmetric nasal tip. The alar base is displaced laterally, inferiorly, and posteriorly leading to a widened nasal aperture. There is shortening of the medial crus of the alar cartilage and lack of over-

lap of upper and lower lateral cartilages. The columella and the caudal edge of the septum and anterior nasal spine are deviated to the non-cleft side.⁵⁶

Evolution of unilateral cleft lip repair

Several surgeons, including Rose (1891), Thompson (1912), Blair (1930), Le Mesurier (1949), Tennison and Randall (1952), and Skoog (1974), have contributed to the evolution of cleft lip repair, but the most popular technique was introduced by Millard (1955) who described the rotation–advancement concept. Today various modifications of the rotation–advancement technique by Millard are used to repair the unilateral cleft lip deformity.⁵⁷ In Millard's technique the medial flap is rotated downward to achieve length, while the lateral flap is advanced (Fig. 45.9). It is an extremely versatile procedure that the surgeon can modify or adjust while operating. The advantage of this technique is that the suture line lies on the recreated philtral column and incision allows easy access for primary rhinoplasty to reposition the nasal septum, lower lateral cartilage, and alar base. The main disadvantage is that the inexperienced surgeon requires good surgical judgment during the operation as it is not based on exact measurements. The triangular flap technique, described by Tennison and Randall, is based on exact measurements, can be reproduced well, and used more easily in wide clefts of the lip.⁵⁸

Principles of repair of unilateral cleft lip and nose

An adequate repair of the unilateral lip deformity should correct the alignment of the orbicularis oris muscle, and create a cupid's bow and philtral column on the affected side. In the unilateral defect the normal side can be used as a guide to identify the key

Fig. 45.8 (a–c) Variations of the unilateral cleft lip and palate deformity. The typical features of the abnormal anatomy in UCLP are seen in these photos. There is vertical shortening of the lip at the cleft margins, orbicularis oris muscle fibers terminate medially beneath the base of the columella and laterally beneath the alar base. Fibers of orbicularis oris in the lateral segment are more hypoplastic and do not extend up to the cleft margin. Note the discrepancy of vermillion width with excess vermillion at the cleft margin on the lateral side compared to the medial side. The maxillary alveolus exhibits asymmetry with an upward and outward rotation of the greater segment.

Fig. 45.9 (a) Markings of the key points and incisions for repair of the unilateral cleft lip using the Millard rotation-advancement principle: lengthening the shortened vertical height of the lip on the medial side to match the lateral, and advancing the flap of tissue from lateral to medial. (b) Markings of the key points and incisions for repair of the unilateral cleft lip using the triangular flap technique.

points and to plan the incisions on the cleft side. Despite inherent variations there are some similarities that form the basis of the guiding principles in surgical repair of this deformity (Fig. 45.10).⁵⁷

1. *Rotation or lengthening of shortened vertical height of lip.* The difference in the vertical length of the lip from the height of the cupid's bow to the base of the columella between the non-cleft side and the cleft side indicates the amount of rotation and back cut necessary. The medial lip element (non-cleft side) is rotated inferiorly to achieve adequate length and symmetry of the cupid's bow.
2. *Advancement of flap of tissue from lateral to medial.* The flap of tissue from lateral should be advanced

Fig. 45.10 Unilateral cleft lip repair. (a) Preoperative and (b) postoperative views of lip repair performed by a modified Millard technique.

in to the lip on the medial segment. It is important to release the abnormally inserted paranasal and facial muscles at the alar base by subperiosteal dissection in order to approximate the edges without tension.

3. *Retaining cupid's bow and creating a philtral column.* Approximation of the cleft edges should be achieved without loss of natural landmarks: the cupid's bow, philtral dimple, and philtral column. The scar of union of cleft edges should be placed along a natural line – the philtral column. Creating a good philtral column requires proper approximation of the muscle and tension-free closure of the overlying skin.
4. *Muscle reconstruction.* The muscle bellies should be dissected within the skin and mucosal envelope. The muscles should be approximated with interrupted mattress sutures. The muscles at the base of the columella and ala should be dissected and approximated to help reposition the distorted nasal structures.
5. *Restoration of the alveolar continuity.* If the alveolar segments are closely approximated a gingivoperiosteoplasty can be performed at the time of primary lip repair to achieve a continuous alveolar arch.
6. *Primary repair of the distorted nasal anatomy.* This requires wide undermining of the skin drape over the lateral crura of the alar cartilages and repositioning of the nasal septum with a suture (Fig. 45.11). Long-term results of primary rhinoplasty by McComb and others show that the outcomes are better and there is no decrease in overall size or nasal growth inhibition after primary correction.^{59–61}

Bilateral cleft lip

Surgical anatomy

Bilateral cleft lip repair is much more challenging and the results are often less satisfactory than those of unilateral cleft lip. Complete bilateral clefts of lip are rare, accounting for only 10% of cleft lips and therefore the experience in treating these deformities is limited. The typical anatomical abnormalities that make the bilateral cleft lip deformity so difficult to repair are the absence of muscle in the prolabial segment, resulting in lack of philtral dimple, philtral

Fig. 45.11 These figures show primary nasal deformity correction in the unilateral cleft lip. (a) Wide undermining of the skin drape over the medial and lateral crura of the alar cartilages. (b) Suturing of the alar dome.

columns, white roll margin, and the median tubercle. The prolabium lacks the angular peaks and the typical cupid's bow. The premaxilla is protuberant and sometimes deviated to one side making tension-free approximation of muscle and cleft margins difficult. The orbicularis oris muscle which is in the lateral lip elements inserts at the alar base on each side. The accompanying nasal deformity consists of a columella that is abnormally short, a wide nasal tip, and a flared alar base due to the malpositioned, splayed alar cartilages. The variations of bilateral CLP deformity are shown in Fig. 45.12.

Evolution of bilateral cleft lip repair

The evolution of repair of the bilateral cleft lip over the years has shown that it is best to repair both sides of the cleft lip at the same time. In many centers today, primary nasal correction is performed along with the repair of the lip. The observation that the alar cartilages are splayed and rotated caudally was important in the evolution of primary rhinoplasty in cleft lip repair. The fear of growth interference when

Fig. 45.12 (a, b) Variations of the bilateral cleft lip and palate deformity. These photos show the typical anatomical abnormalities seen in individuals with complete bilateral clefts of lip and palate: lack of muscle in the prolabium, lack of the angular peaks and typical dip of cupid's bow, lack of a definite philtral ridge or dimple in the prolabium, abnormally short and wide columella, lack of adequate labial sulcus depth in the premaxillary area, and flat nasal tip and flared alar base.

nasal cartilage is manipulated during primary repair has been one of the reasons for delaying nasal repair. For many years forked flaps were used to lengthen the columella, but McComb and Mulliken emphasized the importance of early repositioning of the alar cartilages and unraveled the problem of the short columella and broad nasal tip in the bilateral cleft lip. McComb, after reviewing his initial work over a period of 15 years, found that the nostril shape was still abnormal, the tip remained broad, and the columella was very long.⁶² He proposed primary nasal correction by repositioning the alar cartilages through a vertical skin incision.⁶³ Over the years, the techniques that have been used for repair of the bilateral cleft lip and nose deformity include: the straight line closure or veau III operation; Tennison's triangular flap technique (similar to unilateral repair); Millard's technique; Manchester, Skoog, Black, and Mulliken techniques.^{57,64}

Principles of repair of bilateral cleft lip and nose

The basic principles guiding repair of the bilateral cleft lip deformity are: maintaining symmetry; establishing muscle continuity; designing the prolabial flap to achieve appropriate philtral width and shape; forming a cupid's bow and median tubercle from the lateral labial tissue; and finally repositioning the alar cartilages to construct the nasal tip and columella (Fig. 45.13). The principles outlined here are those of the Mulliken simultaneous lip and nose repair.

1. *Establishing symmetry.* Performing both sides simultaneously allows achievement of symmetry.
2. *Designing a prolabial flap of appropriate width.* The design and width of the prolabial flap should be narrow and biconcave to avoid a wide abnormal philtrum as the child grows. This width should be roughly 4mm at the columella base and 6mm at the peak of the cupid's bow. The mucosa of the prolabium can be used either to deepen the sulcus in the premaxillary region or to reconstruct the lip. The author's preference is to use it to deepen the labial sulcus which is usually shallow.

Fig. 45.13 Repair of bilateral cleft lip and palate. (a) Key points to be marked for bilateral cleft lip repair. (b) Designing prolabial flap. (c) Forming cupid's bow and median tubercle from lateral lip elements. (d) Preoperative and (e) postoperative views of a child with bilateral cleft lip repaired by modified Mulliken technique.

3. *Forming the cupid's bow and median tubercle from lateral lip elements.* The prolabium usually has a very narrow strip of vermillion and hence, in the majority of cases, reconstruction of the vermillion in the mid-portion of the lip presents a difficult problem. The incision on the prolabium is made at the mucocutaneous junction and lateral lip vermillion flaps are used to reconstruct the central portion of the vermillion or the tubercle.
4. *Establishing muscle continuity.* In a complete bilateral cleft the prolabium is devoid of muscle fibers. Establishing continuity of muscle beneath the skin of the prolabium is the only way to reconstruct a normal functioning lip. The muscle fibres that are inserted at the alar base on each side are released and reoriented to be approximated in the midline with vertical mattress sutures. This may be difficult, particularly at the upper edge of the lip in wide clefts or a cleft with protruding premaxillae. While a sulcular incision bilaterally beneath the lateral lip elements is essential to mobilize the lip and achieve tension-free closure, the debate has centered on whether the incision should be subperiosteal or supraperiosteal. The author's preference is to perform a subperiosteal dissection following Delaire's principles.^{65,66}
5. *Reconstruction of the nasal tip and columella.* The lower lateral cartilages should be mobilized adequately from the overlying skin by wide dissection and undermining. The splayed cartilage domes can be approached by combining rim incisions with the prolabial flap. The lower lateral cartilages are repositioned anatomically and fixed with interdental mattress sutures to create the tip and columella.
6. *Repositioning the alar base.* The nasal musculature must be mobilized by performing a subperiosteal dissection along the piriform rim and the wide alar base must be cinched with a suture to the base of the anterior nasal spine.
7. *Management of the premaxilla.* A protruding premaxilla in a complete bilateral CLP can impede the approximation of the lip wound edges with a tension-free closure. This can result in a wide scar and a poor cosmetic result. It is therefore important to reposition the premaxilla in the appropriate position with presurgical orthopedics whenever possible.

Repair of cleft palate

The goals of palate repair are to normalize speech by surgical approximation and realignment of the aberrant attachments of the palatal muscles, and to seal the communication between the oral and nasal cavities without fistulae.

Timing of palate repair

The timing of palate repair to achieve optimal speech with minimal facial growth disturbance has been one of the more debated issues in cleft literature. Historically, cleft repair of the hard palate was delayed to minimize impairment of maxillofacial growth. It is now well accepted, and evidence in the

literature shows, that speech outcomes are better when soft and hard palate repair is completed before speech development.⁶⁷ Palate surgery is therefore timed according to the infant's speech developmental stage rather than chronologic age. For most children developing normally, this is around 9–12 months. The majority of the surgeons repair the palate (i.e. hard and soft palate) in one stage before 12 months of age.⁶⁸ Some recommend a two-stage repair with soft palate repair as early as 3–6 months, at the time of primary lip repair, and hard palate by 12–15 months of age.⁶⁹ Children with cleft palate often have other anomalies and it may be necessary to modify the timing of repair in the presence of comorbidities, particularly airway anomalies. Repair of the palate may be delayed up to 14–16 months of age if there are concerns of airway obstruction. Premature babies and infants with micrognathia are particularly at increased risk for postoperative episodes of apnea after palate repair.⁶⁹

Surgical anatomy

Cleft of the palate can range from a minor submucous cleft affecting only the soft palate to a complete bilateral cleft affecting the primary and secondary palate. It is important to look for overt signs of a submucous cleft if there is any suspicion. These signs include a bifid uvula, notching of the posterior nasal spine, or translucency in the mid-palatine region of the soft palate due to lack of muscle.

The muscles of soft palate that help with the function of speech and swallowing include the levator palatini, tensor palatini, palatopharyngeus, palatoglossus, and musculus uvulae. The soft palate in a non-cleft individual acts as a muscular valve that can lift superiorly and posteriorly to appose the pharyngeal wall and achieve velopharyngeal closure during speech. In a child with an unrepaired cleft, the soft palate cannot function as a muscular valve. This is due to the abnormal orientation and attachment of the muscles, primarily the levator palatini. The bundles of the levator on each side are longitudinally directed to insert into the posterior edge of the palatine bone instead of joining in the midline in a transverse orientation and inserting into the palatine aponeurosis (Fig. 45.14).^{70,71} In addition, the sphincter action of the palatoglossus, palatopharyngeus, and superior constrictor muscles at oropharyngeal aperture is compromised leading to velopharyngeal insufficiency. The tensor palatini muscle fibers, which control the opening of the eustachian tube and aerate the middle ear, do not function optimally, often leading to chronic otitis media.

Principles and techniques of palate repair

The main principle of cleft palate repair is to detach and reposition the abnormal insertion of the levator palatini and join the muscles of both halves of the soft palate in the midline at the junction of the middle and posterior third of the soft palate, in order to achieve

Fig. 45.14 (a) The muscle attachments in a normal palate. (b) Note abnormal attachments of muscle in a cleft palate. (c) A cleft of the secondary palate. (d) A bilateral cleft palate where neither palatal shelves fuse with the nasal septum, leaving a wide cleft in the midline.

proper elevation of the soft palate.⁷² In the hard palate, the most important principle is to reflect mucoperiosteal flaps based on the greater palatine arteries which emerge from the greater palatine foramen bilaterally at the postero-lateral area of the hard palate.

Cleft palate surgical treatment dates back to the 1760s when a French dentist, Le Monnier, first attempted repair. Several other surgeons, including Philbert Roux, Carl Ferdinand Von Graefe, and Johann Dieffenbach, subsequently described techniques to repair the palate. It was Von Langenbeck, who first described the use of mucoperiosteal flaps for cleft palate surgery.^{73,74} Kriens, in 1969, first introduced the concept of an anatomical approach to veloplasty by restoring the levator sling.⁷² The choice of surgical technique depends on the type of cleft. At the time of the primary palatoplasty the ears should be inspected. If there is evidence of serous otitis, a myringotomy is

performed and fluid aspirated with placement of grommets or ventilating tubes in the myringotomy incisions.

The two-flap palatoplasty is a commonly used surgical technique for repair of the complete unilateral and bilateral cleft of the palate. The edges of the cleft are incised from the alveolus to the base of the uvula and bilateral full-thickness mucoperiosteal flaps are reflected (Fig. 45.15). The levator palatini muscles are released and dissected to be repositioned horizontally and sutured. Bilateral releasing incisions are made to decrease the tension in the midline.⁷⁵

For the cleft of the secondary palate a Von Langenbeck repair can be used. In this technique bilateral releasing incisions are made and the mucoperiosteum is elevated to complete the stripping and closure of nasal layer, muscle, and oral layers as shown in Fig. 45.16a. The Veau–Wardwill–Kilner (V–Y pushback) technique, named after Thomas Kilner, Victor Veau, and William Wardwill, is used less often for repair of cleft of secondary palate. In this technique the oral mucosa is divided anteriorly, which may lengthen the palate but leaves areas of exposed bone in the anterior hard palate that can potentially cause maxillary growth disturbances. The double reversing Furlow Z-plasty was introduced by Dr Leonard Furlow Jr in 1978.⁷⁶ This technique uses two reversed Z-plasties of the oral and nasal mucosa to repair the cleft. It has two advantages: restoring the normal anatomic position of the levator palatini in the middle and posterior third of soft palate and increasing soft palate length (Fig. 45.16b). Complications of palatoplasty include postoperative bleeding, airway obstruction, wound dehiscence, and fistula formation. Care should be taken to achieve adequate intraoperative hemostasis and careful postoperative monitoring is essential to avoid airway obstruction.⁶⁸

(a)

(b)

Fig. 45.15 (a) Classic two-flap palatoplasty showing two pedicled palatal mucoperiosteal flaps and closure of muscle and nasal mucosa. (b) The two flaps are brought together by good approximation of the oral layer over the nasal layer.

Speech and velopharyngeal dysfunction

Children with palatal clefts are at risk for a wide range of speech problems related to resonance, articulation, phonation, learning, and language delay. These speech abnormalities can be caused by velopharyngeal insufficiency, oronasal fistula, weak lip pressure, abnormal tongue pressure, malpositioned teeth, abnormal jaw relationship, neuromuscular dysfunction, and conductive or sensorineural hearing loss. It is important to identify and associate the cause with effect. Assessment of speech should begin as early as 6 months of age and be monitored throughout adolescence.

Speech in cleft individuals often has a nasal quality. This perceived hypernasality during speech is typically due to incomplete closure of the velopharyngeal port which separates the nasal cavity from the oral cavity during speech production. Typically, velopharyngeal

Fig. 45.16 (a) The Von Langenbeck technique of palatoplasty is generally used for clefts of the secondary palate. (b) Schematic diagram of Furlow Z-plasty technique, showing the reverse opposing double Z-plasty of muscle and mucosa.

ryngeal insufficiency (VPI) refers to the inability of the soft palate and the posterior and lateral pharyngeal walls to come together to create a seal during speech production. Nasal air escape during speech may be due to an unrepaired submucous cleft of the palate. This can also occur after repair of the palate, due to improper position of palatal musculature impeding movement and/or insufficient soft palate length.

Assessment of speech for VPI has to be both clinical and instrumental. Clinical assessment of resonance characteristics is best performed as a child's articulatory repertoire develops. Non-instrumental testing utilizing visualization of airflow with a reflecting mirror and nasal pinching often assists with the prediction of velopharyngeal function during speech. If deficits are identified, then further assessment using nasendoscopy to assess posterior and lateral pharyngeal wall motion or videofluoroscopy is indicated. Nasopharyngoscopy is a diagnostic tool for evaluation of velopharyngeal function that helps the surgeon to make a decision regarding the need for therapeutic intervention. Small-diameter pediatric flexible endoscopes with a good light source and topical anesthetic for nasal mucosa will help children become more compliant with this procedure.

Studies show that the need for surgical correction of VPI ranges from 4–30%.^{77,78} The most effective method for correction of VPI is controversial but the choice of the procedure depends on cause and where abnormality is found: lateral or posterior pharyngeal wall.⁷⁹ A posterior flap pharyngoplasty is indicated when there is limited or lack of posterior wall motion. The flap may be superiorly or inferiorly based. A superiorly based flap, with the base at the level of the tubercle of the atlas and insertion into the soft palate, is more popular than the inferiorly based

flap. A lateral pharyngoplasty is advocated for managing decreased lateral wall motion by creating a dynamic sphincter to control the size of the pharyngeal orifice. This was first described by Orticochea and modified by Jackson.⁸⁰ The sphincter is created by posterior tonsillar pillars, including the palatopharyngeus muscle, which are raised and sutured end to end.⁸¹

Correction of oronasal fistulae

One of the complications of primary cleft palate repair is failure of healing or breakdown of wound resulting in oronasal fistulae. Fistulae can occur at any location in the hard or soft palate and may cause nasal air escape as well as regurgitation of oral fluids. The reports on incidence of fistula formation are variable and range from 2–43%. Incidence of oronasal fistulae depends on several variables, including experience of the surgeon and age at the time of repair; it is less often related to the type of repair and severity of cleft deformity. The most significant variable seems to be the experience of the surgeon.^{77,82,83}

Repair of the fistula varies according to its anatomical location, whether it is in the anterior or posterior part of the palate. Various local pedicled flaps have been described to close the defect. Posteriorly or anteriorly based tongue flaps, musculo-mucosal flaps based on the facial artery, a temporalis flap, or local palatal mucoperiosteal flaps can be used to close fistulae. More recently, interpositional grafts made of acellular dermis have been used to achieve tension-free closure of oronasal fistulae.⁸⁴ It is important to have at least a two-layered closure without tension and maintain good supply to the flap in order to

achieve a watertight seal of the defect without recurrence. Almost all of the fistulae can be repaired by local pedicled flaps as described above. However, occasionally a vascularized flap may be helpful in closure of a scarred palate with a large defect.

Orthodontic management of the cleft individual

The orthodontist plays an important role in the care of the cleft individual during infancy, mixed dentition and permanent dentition (Table 45.3). Presurgical orthopedic treatment is facilitated by the orthodontist between 2–10 weeks after birth in infants with wide clefts and poorly aligned alveolar segments or a protruding premaxilla. In the early mixed dentition phase, children with complete clefts of lip and palate often have a posterior and anterior crossbite. The crossbite is asymmetric in unilateral clefts, affecting mainly the lesser segment or cleft side. In bilateral clefts, there is collapse of both lateral segments with a bilateral posterior crossbite and protrusion of the premaxilla. The goal of orthodontic treatment in this phase is to prepare for repair of the alveolar cleft by expanding the maxillary alveolar segments, and correcting the position of rotated maxillary incisors. The use of a quad helix or a screw expansion device allows greater expansion in the anterior maxillary arch (Fig. 45.17).

Monitoring facial growth during childhood and early adolescence helps to identify early signs of maxillary hypoplasia and allows intervention if indicated. Maxillary growth may be restricted in the vertical, transverse, and antero-posterior dimensions in chil-

dren with complete CLP. These children may benefit from maxillary protraction using a reverse-pull headgear or early maxillary osteotomy and distraction osteogenesis to minimize the severity of deformity.⁸⁵ The typical orthodontic treatment for a cleft patient following the eruption of the permanent teeth consists of maintaining maxillary arch width after repair of alveolar cleft, and alignment of teeth with full fixed appliances. This should be timed appropriately based on need for orthognathic surgery, the individual's growth potential, and ability to cooperate and maintain oral hygiene. Extraction of teeth may be necessary, particularly in the mandibular arch, if there is arch length deficiency. When surgery is indicated orthodontic treatment is coordinated with timing of growth completion, which is around age 15–16 years for females and 17–19 years for males. It is important to integrate the plan for the replacement or substitution of the absent maxillary lateral incisor and any other missing teeth into the orthodontic treatment plan.⁸⁶

Alveolar cleft repair

The primary goal of alveolar cleft repair is to establish bony continuity of the maxillary alveolar ridge, provide bone support for the teeth adjacent to the cleft, and seal the communication between the nose and oral cavity when there is a patent oronasal fistula. A successful alveolar bone graft should facilitate eruption and orthodontic movement of teeth in the line of the cleft (most often the maxillary canine), maintain the health of the periodontium of teeth adjacent to the cleft, provide alar base support, and improve nasal symmetry.^{87–89} Gingivoperiosteoplasty performed at the time of primary lip repair may seal the oronasal communication but does not always preclude the need for a bone graft. Some studies show that at least 40–50% of these patients require bone grafting in the

Table 45.3 Orthodontic management in cleft individuals

Age	Treatment
2–10 weeks	Presurgical orthopedics
6–10 years	Phase I orthodontics: Maxillary expansion for alveolar bone grafting Maxillary protraction with face mask when indicated
10–14 years	Maintain maxillary expansion and alignment of teeth Monitor facial growth and eruption of permanent teeth Orthodontic treatment with distraction of maxilla if deficiency is severe
14–18 years	Phase II orthodontics: Orthodontic treatment with full fixed appliances to align teeth Prepare for orthognathic surgery when indicated Extract teeth if mandibular arch is crowded Decide whether to replace/substitute the absent maxillary lateral incisor

Fig. 45.17 Orthodontic expansion in a bilateral cleft of lip and palate. (a) Collapsed alveolar cleft segments with decreased anterior maxillary arch width. (b) This maxillary expansion device allows greater increase in arch width in the anterior region more than the posterior region. (c) Maxillary width being maintained after expansion.

future.^{90–92} More recently, Meazzini *et al.* have shown that patients who had a gingivoperiosteoplasty at the time of primary repair did not require bone grafting at a later date; however, they report a greater need for surgical correction of maxillary hypoplasia.⁹³

The timing, source of bone, the surgical technique, perioperative management, and outcome of bone grafting have all been studied and debated. The terms primary bone grafting (2–5 years of age) secondary bone grafting (7–11 years of age), and late secondary bone grafting (14–18 years of age) have been used to define the time of alveolar cleft repair.^{94,95} The majority of the centers use secondary alveolar bone grafting in the mixed dentition phase between the ages of 7 and 11 years, after maxillary expansion. Typically, this coincides with one half to two thirds of root development of the maxillary canine or lateral incisor (if present) in the line of the cleft. Completion of the maxillary expansion prior to grafting provides adequate access to the cleft defect and aligns the cleft segments better.

The gold standard for the grafting material has been particulate corticocancellous bone marrow harvested from the iliac crest, which was first described by Boyne and Sands.⁹⁶ Other sites that have been described include rib, symphysis, calvarium, and tibia.⁹⁷ More recently, the use of bone growth factors, such as recombinant human bone morphogenetic protein-2 (rhBMP-2), has been shown to be effective in grafting the defect. BMP-2 promotes differentiation of pluripotential cells into cells that can form new bone in the defect. This eliminates donor site morbidity and minimizes hospital stay and postoperative pain and discomfort.^{98–100}

New imaging techniques, such as cone-beam computed tomography, allow more accurate assessment of the volume of the bony defect before surgery and radiographic outcome of the grafted alveolus after surgery, when compared to the conventional two-dimensional periapical and panoramic radiographs.

The principles of surgical repair are the same for unilateral and bilateral clefts and include: proper closure of nasal floor mucosa to seal the communication between the nose and oral cavity; removal of supernumerary teeth in the cleft defect; filling the defect with cancellous bone; and approximation of the oral mucosa on the labial and palatal aspects to achieve a watertight closure over the grafted bone, as illustrated in Fig. 45.18. In the bilateral cleft, the position of the premaxilla makes the repair more technically challenging. The premaxilla is often inferiorly positioned, and retruded with the incisors located below the level of the occlusal plane. In some instances, the position of the premaxilla can be corrected by presurgical orthodontics, however in others it may have to be corrected by performing a vomerine osteotomy at the time of surgical alveolar cleft repair. The osteotomized premaxilla has to be maintained in position with a splint for 4–6 weeks postoperatively.^{101,102}

Fig. 45.18 Alveolar cleft repair. (a) Schematic diagram of the alveolar cleft showing closure of the nasal and oral mucosa. (Reproduced from Assael, L. (1995) Cleft lip and palate. *Atlas of the Oral and Maxillofacial Clinics of North America* 3(1), p. 31. Copyright © 1995 Elsevier.) (b) The alveolar cleft deformity is visible and nasal mucosa is closed to seal the communication between the oral and nasal cavities. (c) Cancellous bone is packed into the defect after closure of the palatal oral mucosa.

The amount of maxillary arch expansion prior to surgery should be planned and monitored. Too much presurgical expansion of the lateral segments leaves a large palatal defect making it difficult to advance the scarred palatal mucoperiosteal flaps to cover the bone graft, and too little expansion limits surgical access to the alveolar cleft. After alveolar cleft repair, orthodontic tooth movement, if necessary, can be initiated in 3–4 months. The maxillary width achieved by presurgical expansion should be maintained after surgery with a palatal retainer until phase II orthodontic treatment begins at a later date.

Replacement of absent teeth in the line of the cleft

Congenital absence of the maxillary lateral incisor in the line of the cleft can be managed appropriately by closing the space and substituting the adjacent canine in its position or by opening space and replacing it with a fixed or removable prosthesis. The experience at the center for cleft and craniofacial anomalies at the University of California has shown success of implants in grafted unilateral clefts is better than in bilateral clefts. In the bilateral cases the periodontal health of the central incisors is very often compromised, and the lateral incisors are also absent. The substitution of the lateral incisor with the adjacent canine is cost-effective; however, it can result in loss of arch length and decrease in transverse dimension of the maxillary arch. It can also be unesthetic due to the asymmetry in tooth size and shape in unilateral cases. Replacement with an endosseous implant is an option when there is adequate space and bone quantity. There may be inadequate bone at the time of placement of the implant even if the alveolar cleft was repaired previously.¹⁰³ Alveolar ridge augmentation with a cortical onlay graft performed about 4 months prior to placement of the implant will pro-

vide adequate bone height and width for placement of the implant (Fig. 45.19). A removable prosthesis should also be considered when there is loss of premaxilla, severe deficiency of bone height and width with scarring of the overlying soft tissue, and lack of lip support. Use of teeth-supported fixed prosthetic restorations, such as a bridge, across the unrepaired alveolar cleft segments should be avoided, as movement of the cleft segments results in failure of the prosthesis and loss of abutment teeth.

Surgical correction of maxillary hypoplasia

Cleft lip and palate patients exhibit varying degrees of maxillary hypoplasia due to restriction of midfacial growth that is apparent in the sagittal, vertical, and transverse dimensions. This midface deficiency can be attributed partly to the intrinsic reduction in growth potential due to the congenital malformation and, partly to scar contracture following primary palate surgery.^{104–106} The maxillary deficiency caused by the cleft deformity is superimposed upon the genetically inherited skeletal growth pattern. Hence, an underlying inherited pattern of excessive mandibular growth can present as severe midfacial deficiency and a class III malocclusion in a cleft patient (Fig. 45.20). Regardless of the etiology of maxillary hypoplasia, approximately 25% (reported range 14–50%) of cleft individuals undergo surgical correction of maxillary hypoplasia.^{107–110} This wide range highlights the differing indications for skeletal correction by cleft team specialists. Their decisions are influenced by differing treatment philosophies (orthodontic management with dental compensation vs surgical maxillary advancement to address facial esthetics and occlusion more comprehensively), the availability of appropriately trained surgeons, and hospital/government funding. Good *et al.* reported

Fig. 45.19 Replacement of missing lateral incisor. (a) Alveolar ridge augmentation with a cortical bone onlay is often necessary to increase width and height, before placement of an implant in the grafted cleft site. (b) Unilateral cleft with a missing lateral incisor replaced with an endosseous implant.

Fig. 45.20 Maxillary growth in a child with a unilateral cleft lip and palate. (a) Note that the signs of maxillary deficiency are apparent in the profile view at 9 years in this child with a unilateral cleft lip and palate. that the frequency of a Le Fort I osteotomy for correction of maxillary hypoplasia correlated with the severity of clefting.¹⁰⁹

Technical considerations for cleft orthognathic surgery

Surgical correction of maxillary hypoplasia is usually performed after growth is completed, unless indicated earlier for psychological reasons. When the skeletal discrepancy is severe, a combined maxillary advancement and mandibular reduction can be performed as seen in Fig. 45.21. A staged advancement of the maxilla can be considered, particularly when the mandible is in a normal position. Early surgical maxillary advancement before the completion of growth will help to minimize the reverse overjet and potentially avoid or decrease the magnitude of mandibular reduction at a later date. An example of staged maxillary advancement is shown in Fig. 45.22. In the last decade, distraction osteogenesis of the facial skeleton has become popular and facilitated substantial maxillary advancement without the need for mandibular osteotomies and bone grafting.¹¹¹

Orthognathic surgery in the cleft patient is much more challenging than in the non-cleft patient. Anesthetic management may sometimes be difficult due to the presence of a deviated nasal septum and/

or a pharyngeal flap. It may be necessary to use a fiberoptic-assisted technique or pass an endotracheal tube over a more rigid tube or catheter. The vascularity of the labial and palatal mucoperiosteal tissues is invariably affected by previous surgical procedures for lip and palate repair. Drommer and Luhr demonstrated with the use of angiography that the greater palatine arteries were significantly smaller in 10 of 24 sides in 12 cleft patients prior to maxillary advancement.¹¹² When making mucosal incisions to provide access for the osteotomies, care should be taken to maintain a generous buccal pedicle, preserve the greater palatine arteries if possible, and to avoid unnecessary trauma to the palatal and buccal soft tissue pedicles. Failure to do so may result in the loss of attached gingival tissues, bone, and teeth.

The nasal mucosa and palatal mucosa are fused in the region of the cleft due to the primary palate repair. This tissue should be incised close to the nasal floor just prior to the “down-fracture”. Attenuation of scar tissue close to the nasal floor is necessary to free the maxilla during the down-fracture. Mobilization of the maxilla after down-fracture is more difficult due to the palatal scar tissue and/or a pharyngeal flap. In some cases, release or division of the pharyngeal flap may be indicated to reposition the maxilla into the desired position. The primary palatal repair often results in more bone formation and stronger union at

the pterygo-maxillary junction. Use of a curved chisel to osteotomize directly through the maxillary tuberosities rather than the dense bone of the pterygo-maxillary junction is helpful to complete this posterior osteotomy. Complete mobilization to achieve sufficient advancement requires progressive, careful stretching as the tissues are less compliant than normal tissues.

The maxillary deficiency in the vertical, transverse, and sagittal dimensions makes bone grafting a necessity for cleft maxillary osteotomies performed by conventional orthognathic surgery. A persistent oronasal fistula and alveolar cleft defect, when present, require careful soft tissue closure and bone grafting. The maxilla can separate into two segments during the down-fracture and mobilization even when the

(e) Frontal view shows mild deficiency of midface with poor alar base support. (f) Frontal view in smile shows better midface projection.

alveolar cleft site has been previously grafted. Corticocancellous bone harvested from the anterior iliac crest can be used to graft the residual alveolar cleft defect, to bridge the gap at the osteotomy site after anterior and inferior repositioning of the maxilla, and to augment the deficient area at the piriform rim on the cleft side (Fig. 45.23).

Rigid fixation with plates and screws has to be performed carefully as the quantity and quality of bone is often compromised. When there is deficiency of the midface and malar region, adjunctive procedures, such as zygomatic osteotomies or a modified Le Fort I osteotomy, can enhance cheek prominence and facial contours (Fig. 45.24).

The soft tissue of the upper lip may be tight with a shallow vestibular depth and deficient vermilion show that may become worse following maxillary advancement. When closing the incision, incorporating a V-Y design to minimize lip shortening should be considered. Alar flaring is a common problem in

the distorted cleft nose following a large maxillary advancement. An alar base suture passed in a figure-of-eight fashion through the anterior nasal spine will help to maintain a satisfactory alar base width.

VPI after maxillary advancement has been well documented.^{113,114} The predictability of VPI after conventional orthognathic surgery is based on premaxillary speech. If there is moderate to severe insufficiency prior to maxillary advancement it is more likely that individuals will need postsurgical pharyngeal flap or pharyngoplasty. It is therefore important that these patients are thoroughly assessed for VPI prior to cleft maxillary surgery.¹¹⁵

Conventional orthognathic surgery vs distraction osteogenesis

Postoperative stability after maxillary osteotomy is less favorable in the cleft than in the non-cleft patient. Relapse in the cleft individual is mainly due to the inability to mobilize the maxilla adequately. The tight scarred soft tissue envelope of the palate and upper lip limit the ability to mobilize and achieve the desired movement. Despite bone grafting and rigid internal fixation, relapse in the sagittal and vertical dimensions after maxillary osteotomy has been reported in several studies.^{116–121} Distraction osteogenesis can overcome some of the difficulties encountered with mobilization and stability in conventional orthognathic surgery: it is the technique of gradually repositioning the osteotomized bone segments while forming new bone in the gap created by the osteotomy. Distraction osteogenesis is technique-sensitive, costly, and requires patient cooperation and surgical expertise to properly align, place, and activate the device in order to achieve a good outcome.

Polley and Figueroa first described the use of a rigid external frame to distract the maxilla in a series of cleft individuals. They demonstrated a mean advancement of 11.7 mm.¹²² Since then, several centers have reported their experiences in maxillary distraction in cleft individuals using face masks to provide the external anchorage^{123,124} and internal distractors.¹²⁵ A meta-analysis of literature from 1996–2003 by Cheung *et al.* on cleft maxillary osteotomy and distraction osteogenesis showed that the majority of patients who underwent conventional maxillary osteotomies were older (16–20 years) compared to those who had distraction (11–15 years). The mean advancement for both groups was similar but larger maximum advancement was achieved in the distraction group. The most commonly used system was the rigid external distractor (RED) device.¹²⁶ They subsequently conducted a randomized, controlled study comparing maxillary distraction and orthognathic surgery in 29 non-growing, cleft patients. Intraoral distractors were used in 15 patients in the distraction group and routine miniplate fixation for the 14 patients in the orthognathic surgery group. Clinical morbidity and stability were assessed using a ques-

Fig. 45.24 (a, b) Midface osteotomy including the zygoma and infraorbital rim for correction of severe midface deficiency.

tionnaire and lateral cephalometric tracings respectively. It was found that there was no significant difference in clinical morbidity but the maxillary movement in the distraction group was more stable than in the orthognathic repositioning group. Skeletal relapse was evident in the first 3 months following conventional cleft maxillary advancement.¹²⁷ Improved stability and speech, and marked improvement in hard and soft tissue profile were also reported for distraction by other investigators.^{128–131} In a 2-year follow-up of 12 cleft patients with moderate to severe maxillary retrusion who underwent distraction with internal distractors, a mean maxillary advancement of 14mm with good stability was reported by Rachmiel *et al.*¹²⁵ At the Royal Children's Hospital of Melbourne, internal distractors have been used over the past 10 years in select cases. Unlike external distractors, the internal distractors lack three-dimensional control and particularly the ability to manage the vertical vector. Other disadvantages of internal distraction include a limitation of distractor length and the need for a separate procedure for removal. External frames are bulky and uncomfortable, but provide better vector control and changes can be made to the vector during distraction. Also there is no need for a separate procedure to remove the distractor (Fig. 45.25).

For severe maxillary hypoplasia in the cleft patient, distraction is considered an option as an interim procedure during growth. The aim is to minimize or eliminate the need for mandibular reduction where the mandible is within normal dimensions and relationship to the facial structure. Distraction obviates the need for internal fixation and bone grafting but disadvantages include prolonged facial edema and the occasional inflammatory response to the transmucosal presence of the device activation arms. Traditional staged maxillary advancements remain a predictable option for patients, but the ability to produce large advancements using distraction is attractive in those with marked retrusion. Fig. 45.26 illustrates correction of severe maxillary hypoplasia with distraction. As more clinical studies evaluate the results of midfacial distraction techniques in comparison with conventional osteotomies, it is hoped that protocols can be developed to reflect the best timing and indication for each technique.

Surgical correction of secondary lip and nose deformities

The final phase of treatment for the cleft patient involves correction of the residual lip and nasal deformities to achieve balanced facial esthetics. Typically, the lip and nose revision is performed during late adolescence after skeletal correction of maxillary hypoplasia, and after postsurgical orthodontic treatment is completed to provide a stable dental occlusion.

Secondary lip deformities

Secondary lip deformities that require correction are mainly asymmetries or disproportions. For the majority of patients where the primary repair was carefully planned and executed, secondary lip revisions are minor. In unilateral cleft lip patients, the residual deformities include mismatch of the cutaneous–vermillion line, notching of the vermillion or a “whistle deformity”, vertical shortening of the lateral lip element, a hypertrophic scar, and poor muscle function due to a discontinuity of the orbicularis oris.¹³²

Notching or mismatch at the vermillion–cutaneous junction can be corrected by realignment, small triangular flaps, or a Z-plasty procedure. A poorly defined tubercle can be corrected by a V–Y advancement. It is important to differentiate and maintain the zone of wet and dry mucosa when correcting these deformities. Vertical shortening of the lip after a Millard repair is due to underestimation of the vertical height and inadequate rotation of lip on the non-cleft side at the time of primary repair. Shortening of the lip can also result from severe scar contracture. Correction of a prominent scar with inadequate lip length and compromised muscle function requires a full-thickness revision where all three layers (skin, muscle, and mucosa) have to be cleanly dissected and meticulously repaired (Fig. 45.27).

In the case of a poorly repaired bilateral cleft lip, the deformity can present as a tight upper lip with poorly defined philtral columns and cupid's bow, a short and wide prolabium, poor vermillion show in the center, unsightly scars, exposed wet mucosa, and a shallow labial sulcus. Deficiency of the labial sulcus can be corrected by releasing the scar and performing a Z-plasty. In the case of a tight upper lip, an Abbe flap can be used successfully for reconstruction of the upper lip deformity. This is an axial pattern flap consisting of mucosa, skin, and muscle from the lower lip described by Abbe in 1898. The advantages of this flap are that it carries the dimple from the lower lip to form a philtral dimple in the cupid's bow and the scars give the semblance of philtral columns.

Cleft nasal deformity

Asymmetry and distortion of the nasal morphology is often the most obvious feature of an individual with a cleft. Correction of the nasal deformity in cleft individuals is a challenge due to soft tissue distortions, scarring, nasal stenosis, and uneven bony foundations. Primary correction of the cleft nose deformity is performed by most surgeons today. This does not eliminate the need for a secondary rhinoplasty, but better results can be achieved as the deformity may be less severe.¹³³ The pathological anatomy in the unilateral cleft nose is an asymmetric nasal pyramid, hypoplastic maxilla on the cleft side, and hypertrophied inferior turbinate with deviation of the anterior

Fig. 45.25 (a) An internal maxillary distractor (KLS Martin) in place secured above and below the Le Fort I osteotomy. (b) A rigid external distractor (RED) provides skeletal anchorage with the head frame in a young female with maxillary hypoplasia.

nasal spine and base of columella to the non-cleft side. There is inadequate nasal tip support, posterior and inferior displacement of the dome of the alar cartilage, and inward buckling of the ala on the cleft side.¹³⁴ The bilateral cleft nose is less asymmetrical and the predominant deformity is that of a short columella. Other features of the nasal deformity include a broad downward-rotated nasal tip that lacks support, lower lateral cartilage domes that are widely separated, and lateral splaying of the alar rims with nostril apertures more horizontally oriented.

Cleft septorhinoplasty

There is a wide variation in timing for secondary nasal revisions, with some authors recommending early rhinoplasty. Unless there is a particularly strong

psychological indication or severe nasal obstruction, definite secondary septorhinoplasty in the cleft patient should follow skeletal maxillary reconstruction. The total correction of the cleft nasal deformity is best approached by an open rhinoplasty under direct vision. Wide exposure provides access for mobilization and repair of the collapsed and deformed alar cartilages.^{135,136} In unilateral cleft patients, an open rhinoplasty approach is performed using a trans-columellar incision combined with rim incisions. Complete degloving of the lower lateral cartilages and dissection to the cartilaginous septum enables a full septoplasty with relocation of the caudal septum and the harvesting of cartilage grafts if indicated. Dorsal reduction is commonly undertaken with bony osteotomies to restore the bony vault. Additionally, stiffening the columella by a cartilage strut is necessary to provide tip projection and support for a more symmetrical nasal tip. Reshaping the deficient lateral crus may require a batten graft, and alar base repositioning may be required to improve nostril symmetry (Fig. 45.28). In bilateral clefts, various approaches, including a V-Y advancement to lengthen the columella, have been undertaken, but undesirable scarring is often the outcome. The entire prolabium can be used to lengthen the columella and an Abbe flap can be used to fill the upper lip defect.¹³⁷ The goal is to stretch the nasal tip and to dissect and approximate the lower lateral cartilages to achieve a more triangular inferior nasal shape.

Summary

An esthetic smile and normal speech are two important characteristics which give an individual his or her identity, confidence and self-esteem. The ability to restore lip and palate function without jeopardizing growth with various surgical interventions is the key to management of cleft deformities. This requires a thorough understanding of the embryological, physical and psychological development of the child.

Chapter 46

Diagnosis and Treatment Planning for Orthognathic Surgery

Johan P. Reyneke and Carlo Ferretti

The chapter is a modern and extremely relevant overview of how to perform and think in terms of diagnosis and planning for the orthognathic surgical patient. The therapeutic goals should be to establish functional occlusion and harmony between muscles, teeth, and joints. Furthermore one should aim to improve facial balance, correct speech problems, correct abnormalities related to airway compromise, improve stability of orthodontic and surgical results, and also improve dental and periodontal health. Thorough planning is the key to a successful result in orthognathic surgical cases. Orthognathic surgery techniques are described and commented upon.

Correct diagnosis and efficient treatment planning for dentofacial deformities demand a systematic and objective approach. The basic therapeutic goals of orthognathic surgery are directed towards the correction of specific neuromuscular, dento-skeletal, and soft tissue deformities.

In the past the diagnosis and treatment planning for orthognathic surgery started with analysis of the dentition followed by skeletal and esthetic soft tissue considerations of the dentofacial abnormalities. The modern approach in treatment planning, however, focuses more on soft tissue objectives. Consideration is then given to where the dentition should be positioned by the orthodontist to allow for appropriate surgical repositioning of the jaws which would then result in the best possible esthetic result, normal occlusal function, and stability.¹ The authors believe

that this new direction of facial planning will help to avoid treatment errors such as orthodontic dental compensations worsening the facial imbalance of patients. Inappropriate treatment can often lead to poor facial balance, occlusal relapse, periodontal decline, temporomandibular joint problems, and inadequate airway space. It is, however, interesting to note that, when facial harmony and pleasing esthetics are achieved through proper diagnosis and treatment planning, complications such as those mentioned above are often avoided.

Patients present with a wide range of malocclusions and facial imbalances. Most patients with malocclusions will have normal skeletal relationships and will only require orthodontic treatment without compromise or complications (group 1) (Fig. 46.1a). There is a group of patients that will present with

malocclusions combined with a mild to moderate skeletal discrepancy (group 2). The treatment of some of the patients in this group could be managed by dental compensation and an attempt to control growth (Fig. 46.1b). It would be inappropriate to treat patients in this group with surgery if an acceptable result could be achieved by orthodontic treatment alone. For these cases it is, however, important to explain, demonstrate, and discuss the downside of the expected compromise result (Fig. 46.2). The third group of patients will present with moderate to severe facial imbalance and malocclusion that will require combined orthodontic and surgical treatment (Fig. 46.1c). There will obviously be borderline cases between the three groups of patients. Most errors and probably the more significant errors occur in the diagnosis, treatment planning, and treatment of borderline cases between group 2 and 3 patients (Fig. 46.3).

The differentiation between the groups of patients with mild (group 2) and severe (group 3) dentofacial

deformities is important and will be influenced by various factors:

- The patient's main concern – for some patients a functional occlusion and straight teeth are their main objective while for others facial esthetics and a balanced profile are more important.
- Treatment time – in most cases the combination of orthodontic treatment and surgery will shorten the total treatment time. This fact may influence some patients' decisions regarding treatment.
- The compromise – worsening of the esthetics as a result of orthodontic dental compensation in severe skeletal discrepancy cases (group 3) may be unacceptable to some patients or make no treatment at all a better option than compromised treatment.
- Affordability – due to inappropriate insurance cover many patients cannot afford the combination of surgery and orthodontic treatment.
- Orthodontist's approach – for various reasons, such as a bad experience as a result of inappro-

Fig. 46.1 (a) The patient illustrated has normal skeletal relations and any malocclusion can be corrected by means of orthodontic treatment alone. (b) The patient has a mild to moderate class II skeletal discrepancy and the malocclusion may be managed by means of dental compensation and growth modification. (c) The patient demonstrates a severe skeletal discrepancy and should be treated by a combination of surgery and orthodontics.

Fig. 46.2 (a) A patient in group 2. (b) The predicted soft tissue result following orthodontic compensation of the dentition. The esthetics and possible instability of the result should be evaluated and discussed with the patient.

Fig. 46.3 (a) A patient in group 3. (b) The soft tissue prediction following orthodontic compensation reveals a poor esthetic result, while a more acceptable result can be achieved following surgical advancement of the mandible (c).

priate surgery or unavailability of specialized surgical treatment in the area, some orthodontists are reluctant to refer patients for orthognathic surgery.

The professional treatment team should have clear objectives in mind when making the diagnosis and developing a treatment plan so the patient can be well informed regarding the best possible treatment approach. The therapeutic goals that should be considered are one or more of the goals listed below:²

- establish a functional occlusion;
- establish harmony between the neuromusculature, the teeth, and the temporomandibular joints;
- improve facial balance;
- correct abnormalities related to airway compromise;
- correct speech problems;
- improve the stability of the orthodontic and surgical result;
- improve dental and periodontal health;
- shorten treatment time.

Introducing the patient to orthognathic treatment concepts

Most patients that may need orthognathic surgery and referral to the orthodontist will be oblivious of the fact that surgical correction may be a treatment option. The patient should therefore be gently but confidently introduced to the concept of surgery. The clinician should provide the patient with a realistic and understandable overview of orthognathic treatment principles and general treatment possibilities in relation to the patient's own specific dentofacial problem. Understanding the patient's concerns, motivation, and expectations will provide insight into the patient's psychological health, and the ease or difficulties to be anticipated when treating the patient in

the future. The following questions may help identify the patient's concerns:

1. What are your concerns or problems?
2. Have you had previous treatment for the condition and what was the outcome?
3. Why is treatment required and why now?
4. What do you expect from treatment?

Some patients may find it difficult to answer these questions and may need time to discuss future treatment with family and friends. Patients' priorities may also differ, i.e. for some patients a normal occlusion and straight teeth are important while for others good facial balance and an attractive smile will be a priority. Further counseling about realistic treatment expectations may be necessary, and it may be best if treatment is delayed until, through psychologic guidance, the patient can cope with treatment realities. There is however very seldom need for the above. The perception of one's own appearance is often the "motor" behind direction and confidence in life. Surgical orthodontic change of facial appearance inevitably has a profound effect on this motor.

Systematic patient evaluation

Following the general patient evaluation which would include a medical history, general dental evaluation, and psychologic evaluation (where indicated), a clinical evaluation of the face is carried out. Although orthognathic surgery is usually carried out on healthy individuals it does not preclude the significance of obtaining an appropriate and current medical history as it may affect treatment planning and help the surgeon prevent potential life-threatening complications. The clinical assessment of the face is the most valuable of all diagnostic procedures and should be performed in a systematic fashion with the patient seated comfortably in natural head posture and the teeth in

centric occlusion. Orthodontic and surgical treatments are planned to produce ideal function in centric occlusion. All examination data should therefore be recorded in centric occlusion. However exceptions to the rule would be patients with vertical maxillary deficiency and severe closed bites. To evaluate these patients' lips and upper incisor–lip relationship, they should be examined with their teeth apart and lips just touching. Balance, proportions, and harmony between the various facial structures are more important than numerical values. Only abnormal data should be recorded and the clinician should guard against becoming overwhelmed by a myriad of irrelevant data.

At the first consultation the clinician should, based on first impressions and without data from special investigations, pose the following questions:

1. What is the basic diagnosis of the face? Vertical problem, horizontal problem, maxillary antero-posterior excess/deficiency, mandibular antero-posterior excess/deficiency, etc.
2. What surgery would be required to correct the problem? Superior repositioning of the maxilla, advancement of the mandible, genioplasty, etc.
3. Where would I like the orthodontist to position the teeth to allow for the intended surgery, to achieve facial harmony, and to ensure stability of the results?

Facial evaluation

Several textbooks dedicated to orthognathic surgery and many publications in the medical and dental literature have comprehensively dealt with facial, cephalometric, and dental occlusal analysis as well as many special investigations available to assist in the diagnosis and treatment planning of patients with dentofacial deformities.^{1–3} It is the aim of the authors of this chapter to give the clinician a somewhat different approach to the analysis and diagnosis while still using some basic cephalometric and clinical parameters considered to be the norm for facial form and function.

Whilst the skill to identify esthetically pleasing faces is common to humanity, medical professionals have distilled and crystallized what it is that defines facial esthetics. Of necessity this has been reduced to numerization of facial characteristics which are then compared to normal values. However experienced surgeons have the ability to identify those facial features which detract from facial harmony without resorting to cephalometrics. This ability to identify facial harmony or the lack thereof is a skill attained after viewing many faces over many years. The authors' aim is not to undermine the value of adjunctive assessments such as cephalometrics and dental casts to orthognathic treatment planning, as these are critical contributors to treatment planning. However, they wish to facilitate the development of facial

assessment skills in surgeons embarking on a career in orthognathic surgery.

Facial esthetics is the cumulative result of optimum proportional relations of the esthetics subunits which make up a face. This interdependence makes the assessment of an individual facial component meaningless (i.e. we cannot comment on the antero-posterior position of a mandible until we see the rest of the face it belongs to). Moreover the arbitrary subdivision of the face into thirds is of limited value as the effects of treatment in a single jaw may stretch across two of three facial thirds and a single jaw may contribute to disharmony of more than a single third. It is challenging to formalize a qualitative facial assessment due to the fact that visual examination of a face automatically and instantly assesses facial harmony. Therefore some degree of facial subdivision is required to assist in facial description. The authors believe a more pragmatic approach to facial assessment is to divide the face into zones of influence, i.e. zones which can be modified by orthognathic surgery. Thus the face can be divided into an upper **forehead complex** (extending inferiorly from the hairline to a line connecting the eyebrows across the glabella), an intermediate **oculonasal complex** (extending inferiorly from the forehead complex to a line extending from the lower border of the zygomatic arch curving upwards to the infraorbital foramen, on to the nose above the supratip break continuing on to the opposite side), and finally the lower **gnathic complex**. This latter complex is subdivided into an upper maxillary component (which extends from the lower aspect of the oculonasal complex to a curved line extending along the lower margin of the upper lip, or the lower edge of the incisor teeth if these are visible below the upper lip, to the angle of the mouth and proceeding in a curvilinear fashion to the lower attachment of the auricle) and a lower mandibular component, which extends to the lower border of the mandible and contains in its anterior aspect the oval mental subunit which delimits the soft tissue chin (Fig. 46.4).

With this subdivision in mind one can proceed to facial evaluation. It is a critical point to remember that facial evaluation is not the search for deviation from the norm of a single facial unit but the search for proportion (e.g. a face that is vertically excessive means that, in relation to the transverse dimension, the face is excessively long and not that it is longer than another face (Fig. 46.5). By increasing only the vertical dimension facial harmony is lost, but by increasing both transverse and vertical dimensions harmony is restored.

Most soft tissue discrepancies are indicators of underlying dental and/or skeletal deformities. Knowledge of the soft tissue problems and the relationship with the supporting hard tissue elements (dental and skeletal) will give the clinician a good idea of the orthodontic tooth movement and surgical repositioning of the jaw(s) required for correction of both the hard and soft tissue problems. Some key

Fig. 46.4 The facial division into oculonasal, maxillary, and mandibular complexes (the latter including the genial sub-complex).

soft tissue parameters used for an overview of facial esthetics and the interpretation and differentiations of the possible underlying deformities are listed below.

Profile view

Nasolabial angle

The angle is measured between the columella of the nose and the upper lip and should range from 85° – 105° (Fig. 46.6, Table 46.1).

Lip–chin–throat angle

The angle is formed between the lower lip, the lower border of the chin and the throat and should measure $110 \pm 5^{\circ}$ (Fig. 46.7, Table 46.2).

Chin–throat length

This is measured from the angle of the throat to the soft tissue menton (Fig. 46.8). A length of 42 ± 6 mm is considered to be normal. This measurement can only be meaningful with the patient's head in natural posture. This measurement is significant in assessing the severity of mandibular antero-posterior excess or

Fig. 46.5 The importance of the concept of facial proportion is illustrated by digitally modifying a face with manmade ideal proportions (Venus de Milo). The first image shows a harmonious balance between vertical and horizontal dimensions. Maintaining the transverse dimension but increasing the vertical results in loss of proportion. Increasing both re-establishes harmony. This emphasizes that facial esthetics are not a question of absolute values but more importantly of achieving proportion.

Fig. 46.6 The nasolabial angle is measured between the columella of the nose and the upper lip. The angle should be $90 \pm 10^{\circ}$ and is a guide to the upper lip support by the maxillary incisors. It is, however, also influenced by the decreased vertical dimension due to maxillary vertical deficiency.

Table 46.1 Nasolabial angle.

Acute angle	Obtuse angle
Upper incisor protrusion	Upper incisor upright or retro-inclined
Drooping nasal tip	Prominent or hanging columella
Class III occlusion	Class II occlusion
Deep bite	Open bite
Maxillary vertical deficiency	Maxillary vertical excess

Table 46.2 Lip–chin–throat angle.

Acute angle	Obtuse angle
Mandibular antero-posterior excess	Mandibular antero-posterior deficiency
Thin patient	Presence of submandibular adipose tissue
Class III occlusion	Class II occlusion

deficiency as well as differentiating between mandibular antero-posterior excess and maxillary antero-posterior deficiency (Table 46.3). For a patient with class III malocclusion and normal chin–throat length, maxillary deficiency should be suspected.

Upper lip length

The upper lip length is measured from subnasale to lower lip (stomion superius) and should be 20 ± 2 mm for females and 22 ± 2 mm for males (Fig. 46.9, Table 46.4). Ensure when evaluating the lips that they

Table 46.3 Chin–throat length.

Increased length	Decreased length
Mandibular antero-posterior excess	Mandibular antero-posterior deficiency
Class III occlusion	Class II occlusion
Macrogenia	Microgenia

Fig. 46.7 The lip–chin–throat angle is formed between the lower border of the chin and a line connecting the lower lip and soft tissue pogonion ($110\pm10^\circ$). It is most commonly acute in flat or concave profiles with class III dentoskeletal patterns. An obtuse angle is seen in class II malocclusion, mandibular antero-posterior deficiency, and is often exacerbated by microgenia.

Fig. 46.8 The chin–throat length. This is measured from the neck throat angle to the soft tissue pogonion and is pertinent when considering mandibular setback or advancement procedures, genioplasty, and submental liposuction.

Fig. 46.9 A. The upper lip length is measured from subnasale to lower lip (stomion inferius). B. The interlabial gap is measured between stomion superius and stomion inferius. Critically the assessment should be in repose as patients may assume a lip position which may mask vertical excess. The clinician should guard against using this assessment as this measurement only reflects the central incisor exposure under the upper lip. The shape of the lip and the upper lateral incisor exposure cannot be judged on this view.

Table 46.4 Upper lip length.

Increased lip length	Decreased lip length
Less upper incisor exposure	Increased upper incisor exposure
Differentiate from vertical maxillary deficiency	Differentiate from vertical maxillary excess
Toothless look	Gummy smile
Adequate lip seal	Increased interlabial gap

are in repose. During treatment planning it should be kept in mind that the upper lip length will increase with age.

Interlabial gap

The interlabial gap should be assessed with the lips in repose and the teeth in occlusion. The distance between stomion superius and stomion inferius is measured and should be 0–4 mm (Fig. 46.9, Table 46.5). If the lips touch when the teeth are in occlusion the upper incisor–upper lip relationship should be assessed with the jaws slightly open and the lips in repose.

Fig. 46.10 (a) The facial contour angle is the angle between the upper facial plane (glabella–subnasale) and lower facial planes (subnasale–pogonion) and should be $-11 \pm 3^\circ$ for males and $-13 \pm 3^\circ$ for females. If measured above subnasale the figure is expressed as negative and below as positive. This measurement is an indication of the convexity or concavity of the face. An increased angle generally suggests a relative or absolute mandibular deficiency and a decreased angle a relative or absolute mandibular excess. Differentiating relative from absolute deviations from the norm requires an assessment of the vertical and antero-posterior position of the maxilla. (b) Vertical alteration of the maxillary height, superior repositioning or downgrafting of the maxilla, the mandible will autorotate either counterclockwise or clockwise at the condyle.

Table 46.5 Interlabial gap.

Increased interlabial gap	Decreased interlabial gap/over closed
Increased incisor exposure	Less incisor exposure. Assess with lips apart
Gummy smile	Less than the full incisor tooth crown exposed
Mouth breathing	Over closed appearance
Vertical maxillary excess	Vertical maxillary deficiency/deep bite
Short upper lip	Long upper lip
Excessive vermillion exposure	Less vermillion exposure

Table 46.6 Facial contour angle.

Increased facial contour angle	Decreased facial contour angle
Mandibular antero-posterior deficiency	Mandibular antero-posterior excess
Maxillary antero-posterior excess	Maxillary antero-posterior deficiency
Microgenia	Macrogenia
Vertical maxillary excess	Vertical maxillary deficiency
Class II occlusion	Class III occlusion

Facial contour angle

The angle between the upper facial plane (glabella–subnasale) and lower facial planes (subnasale–pogonion) is an indication of the convexity or concavity of the face. The angle, when measured above subnasale, is expressed as negative and should be $-13 \pm 2^\circ$ for females and $-11 \pm 2^\circ$ for males (Fig. 46.10a, Table 46.6). Although it is an indication of the antero-posterior relationship between the glabella, subnasale, and pogonion, the measurement is certainly influenced by the vertical dimensions of the facial structures. The mandible will autorotate around

the condyle as a result of vertical problems, i.e vertical maxillary excess, vertical maxillary deficiency, increase or decrease in posterior mandibular height, and open or deep bite, and thus the antero-posterior position of the pogonion will change (Fig. 46.10b).

Labiomental angle

The chin forms a very important part of the total facial form and harmony; as with all parts of the face, the chin should be evaluated in relation to all the aspects of the face and evaluated separately for harmony. The lower lip, labiomental fold, and the chin button should form a harmonious S-shaped curve and the depth of the labiomental fold should divide the chin (from stomion superius to soft tissue menton) in an upper third and lower two thirds. The labiomental angle is formed by the intersection of the lower lip and chin measured at the soft tissue B-point (Fig. 46.11). The angle should be gently curved (mean = $120 \pm 10^\circ$) (Table 46.7). Chin contour is just as important as chin position. It is therefore important to note that genioplasty should be performed to improve the shape and contour of the chin and not to essentially place the soft tissue pogonion on its ideal antero-posterior position.

Table 46.7 Labiomental angle

Acute angle	Obtuse angle
Increased overjet	Anterior crossbite
Class II occlusion	Class III occlusion
Macrogenia	Microgenia
Deep bite	Open bite
Lower incisor protrusion	Retroclined lower incisors
Vertical chin deficiency	Vertical chin excess

Fig. 46.11 The labiomental angle is formed by the intersection of the lower lip and the chin and is measured at soft tissue B-point. The angle should be gently curved (mean = $120 \pm 10^\circ$). Since both lower lip position and chin position can affect the labiomental angle, a deviation from ideal requires differentiation between lower lip and chin effects (or a combination of both).

Frontal view

Facial form

The relationship between the height and the width of the face has an important influence on facial form and harmony and should also be correlated with the patient's overall body build (i.e. short and stocky vs long and thin). The height-to-width proportions are 1.3:1 for females and 1.35:1 for males (Fig. 46.12, Table 46.8). The bigonial width should be approximately 30% less than the bizygomatic dimension and the width and shape of the chin should form a harmonious part of the overall facial contour.

Transverse dimensions

The normal interpupillary distance should be 65 ± 3 mm while the intercanthal distance should measure 32 ± 2 mm. Vertical lines drawn through the medial canthi should coincide with the ala of the nose while vertical lines drawn through the medial margins of the irides of the eyes should coincide with the corners of the mouth. For black people this distance would be slightly increased. The orbital dimensions cannot be changed unless craniofacial surgery is contemplated. The measurements will, however, give the clinician an indication of harmony between the nose, the mouth, and the eyes. The bigonial width should be

approximately 30% less than the bizygomatic width (Fig. 46.13a, b). The alar base width will be an important consideration as Le Fort I osteotomy, especially superior repositioning and advancement of the maxilla, may increase the width of the base of the nose. Surgical precautions should be taken to control unwanted nasal changes following Le Fort I osteotomy. The width of the nasal dorsum should be approximately half of the intercanthal width while the width of the nasal lobule should be two thirds of the intercanthal distance. The form and shape of the nose are not only important in the diagnosis and the possible

Table 46.8 Facial form.

Narrow face	Broad face
Long face	Short square-shaped face
Class II and/or open bite	Class II deep bite
Vertical maxillary excess	Vertical maxillary deficiency
Decreased intergonial distance	Masseter hyperplasia
Narrow nose	Broad nose
Microgenia (narrow chin)	Macrogenia (broad chin)
High mandibular plane angle	Low mandibular plane angle
High occlusal plane angle	Low occlusal plane angle

Fig. 46.12 Facial form is a guide to the vertical and transverse proportions of the face. (a) A leptoprosopic facial form. Since the transverse dimension of a face cannot be significantly altered it is pragmatic to assume that the long face has a vertical dimension too large for its transverse dimension. (b) A dolichoprosopic facial form. The short face has a vertical dimension too small for its transverse dimension.

Fig. 46.13 (a) The transverse facial dimensions and facial form. (1) The width of the medial margins of the irides of the eyes should coincide with the corners of the mouth, (2) the medial canthal width should be equal to the alar base width, (3) the bigonial width should be 30% less than the (5) bizygomatic width, (4) the width of the chin should be in harmony with the rest of the face (female chins are in general narrower than the chins of males). (b) Left: a patient with a V-shaped face. The bigonial width is more than 30% less than the bizygomatic width. The patient on the right has a broad square face. The bigonial width and bizygomatic width are almost equal. (c) Left: a patient with a dolichoprosopic facial form as a result of bilateral masseter muscle hypertrophy. Right: the excessive width at the mandibular angles was reduced by partial osteotomy of the mandibular angles and reduction of the masseter muscles. (d) Left: a patient with a V-shaped facial form and a narrow chin. Right: the form of the face is changed to a more oval shape by widening the chin by means of a two-piece genioplasty.

surgical correction of a nasal deformity but consideration should also be given to negative as well as positive effects that orthognathic surgery may have on the nose. Abnormal interpupillary and intercanthal distance are often observed in syndromic patients and can only be altered by means of craniofacial surgery. The width of the midface can be altered by means of either onlay grafts on the zygomas or zygomatic osteotomies. The mandibular angle width can be reduced by means of surgical reduction of the angles and/or reduction of the masseter muscles (Fig. 46.13c), while this dimension can be increased by subperiosteal onlay implants. The transverse dimension of the chin (narrowing or widening) can be altered by a two-piece genioplasty (Fig. 46.13d). Enhancement of the transverse esthetics can be performed by differential change of the anterior and/or posterior width of the chin.⁴

Vertical evaluation

In the vertical dimension the face can be divided into three equal parts: (1) the upper third, from the hairline (trichion) to glabella; (2) the middle third, from glabella to subnasale; and (3) the lower third, from subnasale to menton (Fig. 46.14). Orthognathic surgery can generally influence the lower third and also have some effects to the middle third. However as mentioned previously it may be more useful to consider the subdivision of the face into forehead, oculonasal, and gnathic complexes to better describe the effects of maxillary and/or mandibular derangements.

Table 46.9 shows effects of increased and decreased middle third. In assessment of the lower third, lip thickness, the amount of vermillion exposure, and the severity of the cupid's bow should be noted (Table 46.10). Special attention should be given to the presence of a gummy smile as well as the symmetry of the smile. The amount of gingival exposure when

Table 46.9 Middle third.

Increased middle third	Decreased middle third
Vertical maxillary excess	Vertical maxillary deficiency
Sallow cheeks	Full cheeks
Excessive sclera show below the iris	Normal sclera show
Flat cheek bones	Prominent broad cheek bones
Narrow nose	Short, broad nose

Table 46.10 Lower third.

Increased lower third	Decreased lower third
Vertical maxillary excess	Vertical maxillary deficiency
Increased interlabial gap	Overclosed appearance
Excessive upper incisor exposure under the upper lip	Little or no upper incisor exposure under the upper lip
Flat paranasal areas	Fullness in the paranasal areas
Narrow nose	Short, broad nose
Narrow chin	Broad chin
Class II with or without anterior open bite	Class III closed bite or class II deep bite

smiling and the amount of upper incisor exposure under the upper lip in repose should be correlated. Ideally, the upper lip vermillion should fall at the cervicogingival margin with no more than 2 mm of gingival exposure during smiling. Keep in mind that, although there are several factors to be considered, the amount of incisor exposure or lack of exposure under the relaxed upper lip is the prime indicator of the amount of vertical reposition of the maxilla.

The upper lip vermillion should be about one half of the lower lip vermillion exposure while the depth of the labiomental fold falls about one third down from stomion superius to menton. The length of the upper lip forms one third of the lower third; that is, the lower lip stomion to menton is twice the length of a normal upper lip.

Facial symmetry

The symmetry of the facial midline structures such as the forehead (glabella), nasal tip, upper lip, maxillary dental midline, mandibular dental midline, lower lip, and chin should be assessed (Fig. 46.15a). The clinician should consider whether orthodontic or surgical correction of the dental midlines should be planned. The left-to-right symmetry must be correlated with the facial midline and the face should be reasonably symmetric vertically and transversely. Keep in mind that no face is perfectly symmetric. When evaluating the symmetry of the face it is also very important to assess the presence of any occlusal plane cants. The occlusal plane should be parallel to the interpupillary line, provided that there is no orbital distopia. Surgical correction of an occlusal plane cant often facilitates correction of the asymmetry of the face and the

Fig. 46.14 The vertical assessment of the face for ideal esthetics requires achievement of the proportions set out in the figure.

Fig. 46.15 (a) Facial symmetry is assessed by comparing the left and right sides of the face obtained by a line perpendicular to and passing through the midpoint of the interpupillary line. (b) In addition the parallelism of the interpupillary line and the occlusal plane should be assessed.

severity of the cant should be correlated with the dental and the facial asymmetry (Fig. 46.15b). The vertical discrepancy between the left and right side of the occlusal cant should be noted and correlated with the vertical position of the upper incisor tooth, as correction of the cant will influence the incisor lip relationship.

Intraoral examination

General dental evaluation

The dental history is often a good indicator of the patient's motivation and commitment to future treatment. Previous restorative, periodontal, and orthodontic treatment should be reviewed. Caries, periodontal and periapical pathology, and the presence of impacted teeth should be noted. It is preferred that impacted teeth be removed prior to commencement of definitive treatment or at least 9 months before surgery. When a sagittal split ramus osteotomy is performed, the presence of an impacted tooth influences the difficulty of the surgery and increases the complication rate.⁵ Missing teeth and the need for implants should be evaluated and integrated into the treatment plan. Final prosthodontic treatment is deferred until after completion of orthognathic treatment.

Periodontal considerations

Patients with pre-existing periodontal disease or gingival pathology have an increased risk of disease exacerbation during orthodontic treatment. The amount of keratinized epithelium is important for decompensation of lower incisors in class III cases, and also in interdental osteotomy areas, subapical osteotomies, and genioplasty procedures. Periodontal

disease and inadequately attached gingiva, especially in the lower incisor areas, must be addressed before commencement of treatment. Long-term management, further treatment, and prognosis should be discussed with the periodontist and the patient.

Careful orthognathic surgical techniques must be applied to protect the periodontium and minimize vascular compromise to the bone, gingiva, and teeth. Bone should be maintained around the necks of teeth adjacent to interdental osteotomies and excessive stretching of soft tissue in these areas should be minimized. Poor surgical technique and lack of attention to risk factors may result in devastating periodontal complications.

Occlusal oral function evaluation

Abnormal mastication, swallowing, speech, and mouth breathing should be assessed and noted. The effect the dentofacial deformity may have on normal speech should be evaluated and the patient referred for pretreatment speech evaluation when indicated. Velopharyngeal incompetence and the effect orthognathic surgery may have on the function of the soft palate should be assessed. Thumb sucking, tongue thrust, and lip biting habits should be noted and the effects of these habits evaluated. The size of the tongue and the presence of crenations on the sides of the tongue should be noted and the possibility of macroglossia as an etiological factor of an open bite should be considered.⁶

Temporomandibular joint evaluation

The temporomandibular joints (TMJs) provide the basis for orthognathic surgery. The status of the TMJs should therefore be carefully assessed before treatment, as well as periodically during treatment.

Pretreatment joint dysfunction or undiagnosed joint pathosis can exacerbate postoperative joint problems, and result in pain, limited movement, condylar resorption, joint dysfunction, malocclusion, and relapse. Patients with dentofacial deformities may present in three categories: (1) patients with dentofacial deformities and subjective complaints about concomitant TMJ dysfunction; (2) patients with dentofacial deformities with only signs of TMJ problems; (3) patients with a primary complaint of TMJ dysfunction but with a concomitant dentofacial deformity that is of no concern to the patient.

Systemic conditions that may affect the TMJs as part of a polyarthritic condition, such as rheumatoid arthritis, systemic lupus erythematosus arthritis, ankylosing spondylitis, or scleroderma, should be identified and ruled out.

Pretreatment clinical examination should carefully assess pain, joint noises, function, and maximum mouth opening. Joint pain and neuromuscular pain should be distinguished. Deviation of the mandible during opening may indicate closed lock or fibrous ankylosis. Popping or clicking may indicate disc displacement while crepitations may indicate osteoarthritis, perforation of the disc, or retrodiscal tissue pathology.

Existing joint problems should be diagnosed, documented, and discussed with the patient. Conditions requiring treatment should be carefully planned and sequenced. Generally the joint dysfunction should be first treated conservatively followed by orthodontic alignment of the teeth; the orthognathic surgery is then performed and the joint is re-evaluated. For patients with a history of joint dysfunction, special care should be taken during surgery when the condyles are positioned. If surgery is indicated as treatment for a joint problem the surgery should be performed before orthodontic treatment and orthognathic surgery. Some clinicians, however, prefer to perform joint surgery at the same time as orthognathic surgery.⁷

Condylar resorption should be suspected in patients presenting with a history of having a good occlusion which then slowly deteriorated into a class II anterior open bite malocclusion. Idiopathic condylar resorption is a condition that may develop in young female patients during puberty and growth spurt, with no pain or limitation of jaw movement. The resorption is a progressive process, however it usually stabilizes and the condyle may resorb down to the coronoid notch. Various treatment modalities have been suggested: limiting the compression forces with an “unloading” splint, muscle relaxants, and/or anti-inflammatory medication;⁸ removal of the remaining condyle and costochondral graft reconstruction;⁹ wait for the resorption to stabilize followed by orthognathic correction – Le Fort I maxillary osteotomy, sagittal split mandibular ramus osteotomy, genioplasty;¹⁰ wait for resorption to stabilize followed by distraction.¹¹

The nose

The nose is an important part of the overall facial esthetics and the form and function of the nose can certainly be affected by orthognathic surgery. In many cases nasal reconstruction may form part of the orthognathic treatment plan and, in some cases, nasal reconstruction can be performed concurrent with the orthognathic surgery. Control of the nasal form should also be considered, especially in cases requiring superior repositioning and/or advancement of the maxilla.

The functional and esthetic nasal evaluation should include a thorough examination of the external and internal nasal structures (Fig. 46.16). An intranasal examination should be performed to identify a possible existing deviated nasal septum, hypertrophied turbinates, or nasal polyps. Esthetic concerns should be noted and the nose should be evaluated from a frontal and profile view.

A discussion of detailed esthetic parameters of the nose falls beyond the scope of the text. However, important esthetic factors to consider are the width of the nasal base, and the distance from the base of the nose to the anterior extent of the nares and from the anterior aspect of the nares to the tip of the nose. The prominence of the dorsum, the shape of the nasal tip as well as the acuteness of the supra tip break must also be considered in relation to the intended orthognathic surgery and the physical and/or relative esthetic effects surgery may have on these structures. The length of the columella, the nasolabial angle, and

Fig. 46.16 (a) The nasal projection is evaluated by Goode's method. If BC is greater than 60% of AB, the nasal tip usually appears overprojected. The nasal tip-ala-columella relationship should be a one to one relationship and is an indication of a hanging or retracted columella or a retracted ala. (b) The nasal projection can be evaluated by measuring the angle of the nasal dorsum to a vertical line. The angle should be 34° for females and 36° for males. The relationship between the nasal tip-columella lobule-alar base (1:2) will help to distinguish between paranasal flattening (maxillary antero-posterior deficiency) or overprojection of the nasal tip.

the projection and shape of the nares should be considered, as these aspects may be negatively affected by maxillary surgery.

Radiographic evaluation

The radiographs mostly used as routine in the diagnosis of dentofacial deformities are lateral and postero-anterior cephalometric radiographs, panoramic radiographs, and periapical radiographs. Other radiographic imaging modalities, such as TMJ tomograms, magnetic resonance imaging (MRI), and computed tomography (CT) scans, may be required as determined by the needs of each individual case.

Although clinical evaluation must be the primary diagnostic tool in determining surgical treatment of the orthognathic patient, cephalometric analysis is a helpful diagnostic guide. It helps the clinician: to quantify, classify, and communicate; design a treatment plan by the development of an orthodontic and surgical visual treatment objective; plan for tooth extractions; monitor progress during treatment; study short- and long-term treatment changes; evaluate treatment results and study facial growth.

The cephalometric radiograph should be taken with the patient's head in natural posture, the teeth in centric occlusion, and the lips in repose. There are, however, three exceptions to this rule:

1. In patients with vertical maxillary deficiency the radiograph should be taken with the patient's teeth apart with the mandible rotated open until the lips just part. This view will allow the clinician to evaluate more accurately the upper lip length, the shape of the lip, and the upper incisor–upper lip relationship. It will also assist in planning the correct amount of maxillary down graft required for the case.
2. In patients with severe overclosed bites it is difficult to assess the tooth–lip relationship, the amount of vermilion exposure, and the shape of the lips with the teeth in occlusion. A second radiograph should be taken with the mandible rotated open until the lips just part.
3. Where there is a significant difference between centric occlusion and centric relation, a second radiograph should be taken with the teeth in centric relation.

There exists a myriad of cephalometric analysis, which involves measuring, comparing, and relating various linear and angular measurements of the dental, skeletal, and soft tissues of the face.^{12,13} The clinician should however guard against “playing the number game”. Keep in mind that one is not treating radiographs and the primary goal of treatment should be to make the facial appearance harmonious and to establish a functional occlusion rather than to make the cephalometric measurements normal. It should be emphasized that the primary soft tissue examina-

tion of the profile should be done clinically, guided by cephalometric analytic values.

Diagnosis and treatment planning

The information gathered from the systematic patient evaluation forms a database that will allow the clinician to list all the existing problems. The diagnostic list will include all functional, dental, skeletal, esthetic, and medical problems that may influence the treatment plan. The basic diagnosis should, however, simply describe the case for visualization, communication, and understanding, i.e. class II division 1, mandibular-deficient case or class III anterior open bite, mandibular-excess case.

Careful assessment and consideration should be given to the esthetic concerns, skeletal imbalances, occlusal problems, TMJ and/or myofascial pain, etc., to formulate a treatment plan. It is important to differentiate between various dentofacial deformities that can have similar patterns. For example, a patient with a class II malocclusion may have mandibular antero-posterior deficiency, or maxillary antero-posterior excess, or vertical maxillary excess with clockwise rotation of the mandible, or any combination of the above.

Lateral cephalometric analysis

There is a myriad of cephalometric analysis described in the literature, however the authors use only a selected group of analyses that allows for rapid diagnosis. The clinical soft tissue analysis as discussed previously can be confirmed by analyzing and measuring the soft tissue on the lateral cephalometric radiograph. The hard tissue landmarks on the lateral cephalometric radiograph should be identified and marked and facial planes reconstructed.

Hard tissue landmarks are as follows (Fig. 46.17):

- Nasion (N): the most anterior point on the frontal nasal suture in the midsagittal plane.

Fig. 46.17 Hard tissue cephalometric landmarks

- Orbitale (OR): the lowest point on the inferior orbital rim.
- Sella (S): the center of the sella turcica, as on the lateral cephalogram, which is located by inspection.
- Anterior nasal spine (ANS): anterior tip of the nasal spine.
- A-point (A): the most posterior midline point in the concavity where the lower anterior edge of the anterior nasal spine meets the alveolar bone overlying the maxillary incisor teeth.
- B-point (B): the most posterior midline point in the concavity of the mandible between the alveolar bone overlying the lower incisor teeth and the pogonion.
- Gonion (Go): the point is defined by using two lines, one tangent to the posterior border of the mandibular ramus and the other tangent to the lower border of the mandibular corpus; found by bisecting the angle formed by the two lines and extending the bisector through the curvature of the mandibular angle.
- Menton (Me): the most inferior point on the symphysis of the mandible in the midline.
- Porion (P): the most superior point of the external auditory meatus (anatomic point); machine porion is the uppermost point on the outline of the rods of the cephalometer.
- Condylion (Co): the most postero-superior point on the head of the condyle.
- Gnathion (Gn): the lowest, most anterior midpoint on the symphysis of the mandible.
- Glabella (G): the most anterior point on the frontal bone.

The following constructed hard tissue facial planes are mostly used (Fig. 46.18):

- Frankfort horizontal plane (FH): extends from porion to orbitale.
- Anterior cranial base (SN): formed by a line drawn from sella to nasion.

Fig. 46.18 Hard tissue cephalometric planes.

- Occlusal plane (OP): formed by a line drawn through the mesial cusp contact of the first molar teeth and dividing the incisor overbite.
- Mandibular plane (MP): extends from gonion to menton.

Because the anatomic Frankfort plane (FH) does not always correlate with the clinical impression of the patient's facial deformity, the authors prefer to use the anterior cranial base (SN) as a horizontal reference line.

Skeletal antero-posterior relationships

- Maxillary antero-posterior position (Steiner) (Fig. 46.19). The analysis gives an indication of the antero-posterior position of the maxilla in relation to the anterior cranial base. The angle between the anterior cranial base (SN) and a line drawn between the nasion (N) and A-point is measured and should be 82° for a normal maxilla.
- Maxillary depth angle (McNamara) (Fig. 46.19). The angle between the FH and NA also gives indication of the maxillary antero-posterior position and should be 90° . A line perpendicular to FH should therefore fall on A-point.
- Mandibular antero-posterior position (Steiner) (Fig. 46.19). The ANB angle is measured between SN and a line drawn between N and B-point and it relates the antero-posterior position of the mandible to SN. This angle should be 80° for a normal mandibular position.
- ANB angle (Steiner). This angle gives the clinician an indication of the inter-relationship between the upper and lower jaw. In class II mandibular-deficient cases the angle will be increased while in class III cases the angle will be decreased. An angle of 2° indicates a normal relationship.

Fig. 46.19 The Steiner analysis provides clues as to the horizontal relationship of the maxilla and mandible (ANB angle). The relationship of the jaws to the cranial base is often a less valuable figure as the dimension is affected by the angle of the cranial base.

- Wits appraisal (Fig. 46.20). The Wits appraisal is a linear measurement between the maxilla and the mandible and is not influenced by the anterior cranium. Perpendicular lines are dropped from A-point and B-point, respectively, on to the occlusal plane (OP). The mean measurement in males is BO 1 mm ahead of AO and in females the lines should coincide.

Vertical skeletal relations

The relationship between the skeletal height of the midface and lower face is more important than the actual measurements. The skeletal height of the midface is measured from N to ANS while the lower skeletal height is measured from ANS to the hard tissue menton (Me) (Fig. 46.21). A vertical line is drawn anterior to the face perpendicular to FH. Lines from N, ANS, and Me are constructed perpendicular to the vertical line. The midface and lower facial heights are measured on the line. Normal values should be 53 mm from N to ANS and 65 mm from ANS to Me. The relationship between the two heights is, however, more

Fig. 46.20 The Wits appraisal provides a linear analysis of the horizontal relationship between maxilla and mandible only (i.e. not to the rest of the face).

Fig. 46.21 The vertical proportions in a profile view.

significant than the actual measurements, and should be 5:6. The ANS–Me measurement will be relatively increased in individuals with vertical maxillary excess, vertical mandibular excess, and anterior open bite. The ANS–Me distance will be relatively small in individuals with maxillary vertical deficiency, mandibular vertical deficiency, and deep or closed bites.

Analysis of dental relations

- Upper incisor angulation (Fig. 46.22). According to the Steiner analysis the long axis of the upper incisor tooth should make an angle of $22 \pm 2^\circ$ with the NA line. The labial surface of the incisor tip should be 4 ± 2 mm ahead of the NA line. This measurement is an important presurgical orthodontic indicator.
- Lower incisor angulation (Fig. 46.23). The angle between the long axis of the lower incisor tooth and the NB line should be $20 \pm 2^\circ$ and the labial surface of the tooth should be 4 ± 2 mm ahead of the line. The lower incisor can also be related to the mandibular plane and should form an angulation of $90 \pm 5^\circ$ with the MP. This angle gives the clinician an idea of the amount of dental compensation for skeletal discrepancy present.
- Mandibular plane angle (Steiner) (Fig. 46.24). The mandibular plane is constructed by a line connecting the gonion (Go) and the menton (Me). The angle between the mandibular plane and SN should be 32° . Individuals with high mandibular plane angle would tend to have class II malocclusions, vertical maxillary excess, and anterior open bites. Patients with low mandibular plane angle will tend to have deep bites and may be vertically deficient with overclosed bites.

Fig. 46.22 (a) The upper incisor angulation can be referenced against the lower incisor ($131 \pm 5^\circ$), and (b) the base of the skull (106°) to give an idea of incisor pro- or retroclination. In general, however, the most important determinant of upper incisor angulation should be alveolar angulation and to ensure the tooth is in the central trough of bone. The labial surface of the upper incisor should be 4 mm ahead of the NA line.

Fig. 46.23 (a) The lower incisor angulation can be referenced against the upper incisor ($131 \pm 5^\circ$), and (b), the mandibular plane ($90 \pm 5^\circ$) to give an idea of incisor pro- or retroclination. Due to the extreme narrowness of the lower anterior alveolus, especially in class III cases, great care must be taken when considering correction of incisor angulations. The alveolar angulation should form the basis for determining where the lower incisor can be placed. The labial surface of the lower incisor should be 4mm ahead of the NB line.

- Occlusal plane angle (Fig. 46.24). The occlusal plane angle is formed between a line drawn through the region of the overlapping cusps of the first bicuspids and first molars bisecting the incisal overbite (occlusal plane) and the anterior cranial base. The normal value for this angle is 14° . The occlusal plane has significant influence on function, esthetics, and treatment planning for double jaw surgery.

Postero-anterior cephalometric analysis

This analysis should be done in combination with the lateral cephalometric analysis for patients with facial asymmetry. The authors find the analysis according to transverse planes and the triangular analysis helpful when assessing individuals with skeletal facial

asymmetry (Fig. 46.25).¹⁴ The hard tissue landmarks on the postero-anterior cephalometric radiograph should be identified and include the following:

- SF: the point where the smaller wing of the sphenoid crosses the medial orbital ridge.
- Anterior nasal spine (ANS): the center point at the base of the nose.
- Jugulare (J): the most superior and medial point on the zygomatic buttress.
- Mastoid (M): the most inferior point on the mastoid bone.
- A: the contact point between the upper incisors.
- B: the contact point between the lower incisors.
- Y: the most lateral point on the buccal surface of the upper first molar. L and R will designate left and right sides.
- Z: the most lateral point on the buccal surface of the lower first molar. The left and right sides will be indicated by L or R.

Fig. 46.25 Postero-anterior cephalometric landmarks.

Fig. 46.24 The occlusal plane angle (α) and mandibular plane angle (β).

- Gonion (Go): the most inferior posterior point on the mandibular angle.
- Menton (Me): the most inferior point in the center of the mandibular symphysis.
- CH: the most inferior lateral point on the anterior inferior border of the mandible. The left and right sides will be indicated by L and R.

Transverse planes

These planes indicate transverse skeletal and occlusal plane cants (Fig. 46.26):

1. Cranial base plane (C plane): connect the left and right CF points and extend laterally.
2. Mastoid plane: connect the left and right M points.
3. S plane: the left and right Go points are connected.
4. J plane: connect the left and right J points.
5. Occlusal plane (OP): this plane is formed by a line drawn connecting the left and right occluding points of the first molars.
6. Chin plane (CHP): the plane is formed by connecting left and right Me points.

Vertical cephalometric midline

This line is constructed by dividing the C plane and mastoid plane and connecting the two points then extending the line to the chin (Fig. 46.26). The line is called the geometrically constructed vertical axis (GM).

Triangular analysis

Triangles can be constructed to evaluate the symmetry of the maxilla, mandible and chin (Fig. 46.27).¹⁵

Fig. 46.26 Postero-anterior cephalometric planes.

1. Maxillary triangle: this triangle is constructed by connecting the midpoint of the C plane with J points on either side.
2. Mandibular triangle: the mandibular triangle is formed by connecting the C point with the left and right Go points.
3. Chin triangle: connect C point with CHL and CHR.

By measuring the long legs of the triangles, the cants of the maxilla, mandible, and the chin can be related to the cranial base. Also by comparing the left and right sides of the bases of the triangles, transverse discrepancies can be assessed. Midline asymmetries of structures such as ANS, menton, and dental midlines should be evaluated in relation to GM. The relationship between the dental and skeletal midlines will indicate if dental midlines should be corrected orthodontically or surgically.

Dental model analysis

Careful analysis of dental models will assist in diagnosis, and help to establish a problem list and develop an orthodontic and surgical treatment plan. Handheld models will also improve the clinician's understanding regarding transverse discrepancies between the upper and lower dental arches and differentiation between relative and absolute crossbites. There are several aspects of dental model analysis that should be considered:

1. Missing teeth (congenital or extracted), broken down or crowned teeth. This information will assist in the decision about the extraction pattern and the mode of space closure, whether orthodon-
